After a short review of the anatomy and physiology of the male sexual system, the author devotes considerable space to the etiology of impotence. He mentions colliculitis as the chief cause, secondarily masturbation, coitus interruptus, coitus reservatus, etc. Much less attention is accorded to psychic impotence than its frequency warrants, and practically no consideration is given to prostatitis and seminal vesiculitis as causative factors. He relates many scientific facts, hitherto fairly well known, and illustrates them with clinical experiences. The illustrations are clear and well selected. The lucid literary style commends this work to those not possessing fluent knowledge of German.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held December 23, 1909.

DR. JOHN O. POLAK IN THE CHAIR.

Recent Cases of Pelvic Suppuration.—Dr. ABRAM BROTHERS presented two cases.

CASE I.—This patient had a pelvic suppuration, due to tuberculosis. She was twenty-three years old, married four years, and had two children, both alive and well. Her menstrual history was negative. Two months ago she complained of pain in the right iliac region which was burning in character, and accompanied by frequent and painful urination. She had a marked leucorrheal discharge. She had had a few attacks of chills and fever. She was treated expectantly with but little relief. One week prior to her admission to the hospital the pain in the right iliac region became worse, the leucorrheal discharge increased, and she had chills, fever, and vomiting. There was dyspnea on admission. The leucocytes numbered 16,000 and the polymorphonuclears were 85 per cent. A mass was readily palpated in the right iliac region and rigidity over the right rectus muscle was present. The temperature ranged from 98° to 103° F., and the pulse was between 90 and 120. On November 23, half a dram of pus was obtained through a posterior vaginal section, not enough to account for the size of the mass, however. Subsequently there was rather a profuse purulent discharge which lasted for several days. On November 20, laparotomy was performed. Dense and numerous adhesions between the omentum, intestines, and adnexa were encountered. The omentum and peritoneum were found to be studded with small and numerous tubercles. On December 7 there were 9,000 white cells and 70 per cent. polymorphonuclears. Since the operation the temperature had ranged between 99° and 104° F. The pathologist reported this to be a case of miliary tuberculosis. Since the operation the patient had remained about the same, except that there was less pain in the right iliac region.

CASE II.—This was a case of pelvic suppuration, due to gonorrhea. The patient was twenty-one years old, married four years, and had never been pregnant. She had had a leucorrheal discharge during the past three years. She was admitted to the hospital November 5, 1909, complaining chiefly of dysmenorrhea, dysuria during the past three months, and sterility. She was a well developed and well nourished woman, with no abdominal symptoms or signs, but she had a temperature which ranged from 99° to 102° F.; once it rose to 103° F. The pulse rate was from 90 to 110. Her husband contracted gonorrhea about three months ago. Laparotomy was performed November 19. She had a very fat abdominal wall. Both tubes were found to be involved in many adhesions to the parietal walls, intestines, and omentum. The adnexa were enlarged, thickened, and inflamed. A double salpingo-oöphorectomy was performed, and a ventral suspension done for a retroverted adherent uterus. The patient made an uneventful recovery, except for a slight subcutaneous suppuration at a point where the fat in the abdominal wall was at least two or three inches thick.

Dr. A. ERNEST GALLANT thought that rather than do a ventral suspension of the uterus in this case, it would have been better to have done a complete hysterectomy. He had seen several cases in which an attempt had been made to suspend the uterus and later it had become necessary to remove that organ. Dr. Gallant recalled a case of tuberculous peritonitis which was operated upon five years ago. There was a leakage through the abdominal wall for eight months, and the patient to-day weighed more than double her former weight. With regard to the vaginal opening, he had learned a lesson some years ago. He attempted to remove what he supposed to be an appendix, through the regular incision, but he found a pus tube above the pelvic brim. Since then he had been very careful to find out whether the trouble was located above or below the brim of the pelvis before opening above or below the pubes. In fat patients this was not always possible.

Dr. WILLIAM S. STONE said that the frequent suppuration of these abdominal wounds in fat subjects was caused by the use of infected sutures; puncturing the fatty tissues resulted in an exudate into the wound of a fatty fluid which invited infection.

Dr. C. CLARENCE SICHEL said that he had seen a great many cases in which the abdominal wound became infected because spaces had been left between the layers of tissues which invited infection; therefore, he was now inclined to place deep supporting sutures, going down to the peritoneum, thus bringing the edges well together. Infection was made less likely by leaving no spaces between the tissues. The majority of the cases reported by Dr. Brothers were better off when attacked from above than from below, draining from above and also through the vagina when it was found to be desirable.

Dr. HERMAN L. COLLYER said that some times one was quite surprised when the abdomen was opened, expecting to find pus tubes, to find something else. The reason the abdominal layers of fat did not unite well was because in the first place the tissues were injured. A second reason was that the pus tube was usually ruptured and the fat became infected. It had been his good fortune to have the fat unite by first intention, but he was always very particular not to bruise the fat. He also used alcohol freely on the fat. In operating for pus tubes Dr. Collyer said it was his habit to first open from below and drain. Then it gave the woman a chance to become pregnant, as many had, after recovery from the evacuation of pus tubes from below. If one wanted to remove the tubes afterward, it was easier and better to have evacuated the infectious pus from below.

Dr. SAMUEL M. BRICKNER said that one point in reference to the treatment of fat abdominal tissues had not been mentioned; that was, when the fat was sutured necrosis of the tissues occurred, and subsequently left an infection. The infection was secondary, not primary, as a rule. In his work he avoided touching the fat at all, simply clipping the skin together. By means of two rolled towels the wound could be readily approximated, and it healed without difficulty. So far as drainage from below was concerned, this subject had long ago been threshed out before the section, but it could be summed up in a few words. In any acute infectious process of the tubes and ovaries, do not operate; when the connective tissue of the pelvis was the seat of an abscess, pointing in the posterior fornix, open from below. In subacute or chronic pus tubes, it was safe to operate from above.

Myomectomy for Fibroids of the Uterus Complicating Pregnancy.—Dr. LOUIS J. LADINSKI reported the case of a woman, thirty-one years old, married ten years, no children, but one abortion two months after marriage. She had not been pregnant since. Her last menstruation occurred five months ago, when she began to "spot" and complained of slight abdominal pains. About October 20 the pains became more severe and she was confined to her bed. The doctor who was then called in made a diagnosis of "tumor complicating pregnancy." Two days after she was removed to the hospital, where she remained under observation for three weeks. During this time she grew steadily worse; the abdominal pains became more and more severe, the abdomen increased in size; she was then anesthetized and was told that a uterine tumor had been removed. This procedure did not, however, improve her

condition, and after another week of expectant treatment she was sent home. On November 28 Dr. Ladinski again saw her in consultation, and had her admitted to Beth Israel Hospital. She then complained of abdominal pains, extreme weakness, headache, nausea, and vomiting. She was anemic, almost cachectic. The red cells numbered 2,400,000, and the hemoglobin was 40 per cent. and polymorphonuclears 77 per cent. On palpation there was noted a distinct, hard, irregular mass occupying the lower part of the abdomen. There was distinct evidence of free fluid in the peritoneal cavity. The uterus was enlarged to about twice its natural size, and was pushed upwards and to the left by this mass. The unusual clinical features presented by this case made the diagnosis very difficult. However, after considering the various possible diagnoses, it was decided that one of two conditions existed: papilloma of an ovary with ascites, or advanced extrauterine pregnancy. On December 4 the abdomen was opened, disclosing an immense amount of free, old, dark colored blood. This was evidently not due to a rupture, but was the result of a diapedesis of blood cells into the peritoneal cavity from the congested abdominal viscera. The mass proved to be a gravid sac containing a five months viable fetus. The placenta was attached to the omentum, the small intestines, the right and left adnexa, from all of which it was separated without any great difficulty. During the operation the patient received an intravenous saline solution. This evidently was a case of tubal pregnancy which, after rupture or abortion, was converted into an abdominal pregnancy. The fetus was a monster, and presented a globular pedunculated mass, about the size of a hen's egg, springing from a pedicle which extended from the ensiform cartilage to the pubes in the median line. This mass was everywhere covered with a thin translucent layer of peritoneum through which might be seen the intestines, the liver, and the heart. The heart, after the operation, pulsated for fully twenty minutes. The sac was seen to contain the entire liver, the stomach, small and large intestines, spleen, pancreas, ureters, upper part of the bladder, and the heart. All these structures passed through a defect in the anterior wall. The right half of the diaphragm was entirely missing. The diaphragm had lost its anterior and right attachments to the chest, and was dislocated downwards so that part of it was within the tumor. The fetus presented the following deformities: There was an imperforate anus; both feet were held in a position of extreme equinus valgus; there was edema of the posterior part of the neck, the occiput, and the frontal regions. The specimen presented by Dr. Ladinski was a celosoma associated with a prolapse of the heart into the hernial sac and an absence of the anal orifice, conforming in some respects to the type designated as agenosoma by Saint-Hilaire.

Dr. Hermann Grad said that the specimen presented by Dr. Ladinski was exceedingly interesting. He thought the doctor was to be congratulated upon making the diagnosis. At present there was a case under his care in the hospital where the question of an abdominal pregnancy was raised. It was impossible to make a definite diagnosis in this case. The fetal parts could be felt quite plainly, this being the woman's twelfth pregnancy. The patient gave various symptoms, pain in the abdomen being the most prominent one. These cases were extremely difficult to diagnose; many times a diagnosis was not possible before opening the abdomen. Dr. Grad asked if it might not be that the abdominal organs of the fetus shown was a case of displacement, and not of faulty development. This would be a very interesting thing to learn. Was the displacement of the abdominal organs due to pressure, or was it really a monstrosity?

Dr. Ladinski said that when he had removed the fetus he immediately proceeded to remove the placenta, which was very closely attached to the abdominal viscera, but he felt that it was better to remove it *in toto*. His results justified him in doing it. Twenty-four hours after the operation he removed the drain, which had been left in merely to check the parenchymatous oozing. The wound healed by primary union. The advantage of removing the placenta in this manner had been forcibly demonstrated in this case by the primary union and by the short convalescence. If the case had been tamponed it would have required a long seige of drainage, with a prolonged convalescence, and the final result, because of the probable presence of peritoneal adhesion, with its consequent after effects, could not be compared with that obtained in this case. The additional hemorrhage caused by the removal of the placenta was inconsequential in comparison. There was no doubt at all about the specimen being a monstrosity.

Unilateral Twin Tubal Pregnancy.—Dr. Eugene H. Pool presented this interesting specimen. It consisted of a Fallopian tube about 12 c.c. in length. The inner part, 4 c.c. in length, was only slightly thicker than a normal tube, but the outer part was greatly enlarged, measuring about 8 x 4.7 x 2.5 cm. The surface of this portion was smooth except at the outer part of the posterior surface, where the tube had ruptured. The interior was filled with an adherent blood clot, at the upper part of which might be seen the placenta and the edge of a thin retracted membrane, the remains apparently of a single amniotic sac. From the placenta passed two cords 3 c.c. long, separated 2 c.c. at their attachments. To each cord was attached a fetus. The fetuses were of the same size and development. The patient from whom the specimen was removed was twenty-seven years old, and was admitted to the hospital on November 1, 1909. She complained of severe cramp-like pains in the left lower quadrant of the abdomen, bleeding from the vagina, and weakness. Her last menstruation began on September 27. She had missed no periods. She had been married seven years, and five months after her marriage she had miscarried at the third or fourth month. She had never been pregnant since. The examination revealed a slight enlarged anteflexed uterus behind and to the left of which could be felt a tender, smooth, immobile mass, evidently the left tube. When the abdomen was opened a moderate amount of fresh blood was found and some blood clots in the pelvis. The mass was brought into the wound and proved to be a much enlarged left tube, which had ruptured and which was bleeding freely. There were two fetuses attached by separate cords to one placenta. In one fetus the arms and legs were contracted and extended for about a minute after exposure to the air. Her convalescence was uneventful.

Dr. Hermann Grad said he had seen one case of twin tubal pregnancies. The patient was brought to the hospital and in a state of collapse. She had a very bad internal hemorrhage. Upon opening the abdomen two small fetuses floated out of the incision from the abdominal cavity. The hemorrhage was terrific, and the patient died before she was removed from the operating table. He said he had never seen such an alarming hemorrhage before. This was the only case of twin ectopic he had ever seen.

Premature Menopause.—Dr. Meyer Maurice Stark read this paper. He defined the term menopause as applying to that collection of phenomena appearing with the cessation of menstruation and comprehending the whole process of senile involution of the generative organs. The period of time over which these phenomena might manifest themselves might vary from one to ten years. He reviewed the results of Dalton's work and called special attention to the fact these investigations demonstrated, that the first changes in connection with the menopause occurred in the ovaries. He did not deal with any pathological features attendant upon the menopause, but only called attention to a condition which occurred. The series

which he presented, and which was taken from the clinic of Dr. Louis J. Ladinski at Beth Israel Hospital Dispensary, included only those cases where the periods, which had hitherto occurred in a normal or abnormal manner, ceased without being affected by internal or external influences and without the occurrence of any previous or subsequent disturbances of the economy, or without the objective demonstration of any disease. This series was composed of patients who in every way seemed to be perfectly well; in fact, they were in better physical condition than before the cessation of menstruation. Statistics were very plentiful as to the usual age at which menstruation ceased. Many authorities cited cases in which menstruation persisted at advanced age. It was, however, the consensus of opinion that any menstruation after the age of 53 should be looked upon as pathological. An inspection of statistics showed that in one-half of all cases the menopause occurred between the ages of 45 and 50; in one-fourth of all cases it occurred between the ages of 40 and 45; in one-eighth of all cases between the ages of 35 and 40, and in one-eighth of all cases between the ages of 50 and 55. Most authorities were agreed that the earlier menstruation began, the longer it was likely to continue. Tilt estimated the average duration as 32 years. Menstruation that ceased before the age of 40 was irregular, and if it ceased before the age of 30 it was premature. Dr. Stark had collected 48 cases from the literature, and of these Dr. Edward Krieger had cited 35. Of these 35 cases, three occurred at the age of 21 years, two at the age of 22, one at the age of 23, one at 24, two at 25, one at 26, three at 27, three at 28, three at 29, and sixteen at 30. Wherever the results of genital examination were recorded in these cases conditions appeared not dissimilar to those occurring at the menopause. Whether or not the conditions observed were the cause or the result of menopause was not at all clear unless one accepted the findings of Dalton, which brought out the fact that the first signs of atrophy began in the ovaries and became quite marked before the uterus began to diminish in size. This fact seemed to lead to the conclusion that the different forms of atrophy of the uterus, in their relation to accompanying amenorrhea or menopause, were dependent on preceding changes in the ovaries, and thus the uterus came to be regarded as the retrograde metamorphosis of a gland which had become functionally useless. The changes, therefore, in the ovarian parenchyma were important factors in the question under consideration. In acute febrile diseases and in the exanthemata the parenchyma of the ovaries sometimes suffered sympathetic changes, and these same primary changes resulted in a cessation of menstruation. Courty had reported three cases in which the menopause ensued after cholera. The hyperplasia resulting from frequently succeeding pregnancies should result in early menopause when one considered the inevitable retrogressive changes following such hyperplasia. Mayer reported a case in which the menopause occurred at the age of 29, after six successive pregnancies. Such agencies as peritonitis and excessive involution of the uterus due to lactation were given as etiological factors. Cases had been reported in which fright and sudden affliction seemed to be the cause of premature menopause. Börner and others gave heredity as an occasional cause of prematurity. Obesity was thought by Kisch to be the cause and not the result of the early cessation of menstruation. Currier stated as a constant rule that a woman under thirty who became obese suffered from amenorrhea or dysmenorrhea, and in addition was usually sterile. It was a noted fact that women began to take on flesh at or after the menopause or, in other words, at a period coincident with sterility. This fact was a feature in many of the cases cited in this paper. Sterility and amenorrhea were the matters concerning which this class of patients usually sought advice. Numerous cases, however, had been reported in which pregnancy had occurred after complete cessation of menstruation, not only in early cases, but in the typical ones. Piron reported a case of a woman 72 years of age who aborted a two months fetus. In Tilt's series of 49 cases of menopause between the ages of 29 and 39, there was an average of three children in 26 women. Of the eight married women in Dr. Stark's series of eleven on which this paper was based, four bore children. The occurrence of 11 cases out of 3,301 cases who presented themselves at the dispensary showed a frequency of one in 300, by no means an insignificant percentage. None of the causes cited figured in the series. The absence of previous or subsequent local or constitutional disease was the rule. They seemed to be from the outset types of irregular or scanty menstruation, in which the ovarian function had worn itself out, so to speak, without impairing the health of the patient. Whether this was due to faulty development of the generative organs could not be stated, though it was difficult to look at the cases in any other light than as presenting an unnatural condition due to some defect or disease. Only those women were included in the series who had been under observation for two years, or those in whom menstruation had been absent for four years.

Dr. Herman J. Boldt said that the instances in which heredity was a factor in premature menopause, so far as his observations went, were comparatively few. He had seen a number of cases in which the menopause was established prematurely, below the middle twenties, but it was impossible to tell definitely just what the cause was. However, in most of the instances that had been under his observation there were atrophic changes, and in about 25 or 30 per cent. these had been the results of traumatic lesions, namely indiscreet curetting, but puerperal infections also played an important part.

Dr. Hermann L. Collyer believed that the statistics presented were to be criticised. Undeveloped uteri could not be compared with perfectly developed uteri. These cases that were reported as having an early menopause at 21 were, unfortunately, in women without a perfectly formed uterus and ovaries. He believed that in the classification of the cases of early cessation of menstruation there should be three, viz., (1) undeveloped uteri, (2) traumatic injuries to the uterus, (3) diseased uteri by specific causes, either gonorrheal or syphilitic. He did not think it was right to include in the statistics those cases of undeveloped uteri because menstruation was liable to cease at any time in such cases.

Dr. Hermann Grad said he had not made a very great study of the subject under discussion, but there were three things that should be noted, viz., (1) menstruation was irregular from its beginning, (2) these women had a tendency to become fat; they also had a masculine appearance, with robust and oftentimes clumsy bodies; (3) when menstruation was irregular and they had borne children, traumatism was frequently at the bottom of the cause of the premature menopause. No doubt many cases were due to undeveloped uteri and ovaries as well.

Dr. Stark said that the classification he presented was his own. Nobody heretofore had taken note of the age when premature menopause should be so classed; he, therefore, placed it at the age of thirty. The cases that occurred under this age were rare.

Election of Officers.—*Chairman*, Dr. Samuel M. Brickner; *Secretary*, Dr. Harry Dawson Furniss.

Pelvic Transplantation Metastases.—Palmer says that rectal examination is absolutely necessary in all abdominal tumors. Of 435 consecutive cases of carcinoma of the upper abdomen, six and one-half per cent. showed pelvic transplantation deposits as the earliest clinical sign of inoperability. Seven and two-tenths of stomach carcinomas had this sign.—*Surgery, Gynecology, and Obstetrics.*

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Annual Meeting, Held January 17, 1910.

The President, Dr. Robert T. Morris, in the Chair.

Election of Officers.—The following officers were elected for the ensuing year: *President,* Dr. Reynold Webb Wilcox; *Vice-President,* Dr. Ransford E. Van Gieson of Brooklyn; *Recording Secretary,* Dr. P. Brynberg Porter; *Corresponding Secretary,* Dr. Frank C. Raynor of Brooklyn; *Treasurer,* Dr. A. Ernest Gallant; *Chairmen:* Borough of Manhattan, Dr. J. Blake White; Borough of The Bronx, Dr. Nathan B. Van Etten; Borough of Brooklyn, Dr. J. Scott Wood; Borough of Queens, Dr. Neil Orrin Fitch; Borough of Richmond, Dr. William Bryan; *Member of the Executive Committee,* Dr. Louis F. Bishop.

Some New Tests for Test-Meal and Feces Examinations.—Dr. Anthony Bassler, in this paper, described his methods and apparatus for examining test meals and feces according to the results obtained by bacterial action. He drew attention to the fallacious results noted in many of the other clinical diagnostic measures, notably the Schmidt and Strausberger test diets, the Schmidt connective tissue test, the Günzberg and Sahli packages, and the Einhorn bead test. He claimed that in nearly all cases of early gastric carcinoma and in latent ulcer no value came from the ordinary methods of test-meal analyses, but much significance might come from the bacterial tests with test meals, and that abnormal bacterial conditions of the colon were more times matters of assumption rather than accurate clinical diagnoses—for not all of the bacterial conditions of the gut showed indol in the urine. He said that the dietetic and neurotic conditions of the stomach did not give more than the merest bubble, but that in ulcer and cancer this was higher, and he described his method of feces work for diagnosing the bacterial conditions of the colon on this basis. In the normal individual the feces and water tests showed a low gas result on the strict meat diet, the ordinary mixed diet showed a higher result, while that of the strict carbohydrate diet was highest of all. When in the nutritive media the gas result was higher than normal, the patient was placed upon a strict meat diet and the watery suspension test performed, at which, should the gas result be higher than a meat diet should give, the diagnosis of the indolic form of chronic intestinal putrefaction was suggested; on the other hand, should the gas result in the nutritive media be lower than normal, the patient should be placed upon a strict carbohydrate diet to see if the gas from the watery suspension of feces still remained below what was ordinarily seen in an individual on such a diet, at which, when the result was positive, the diagnosis of the more common saccharobutyric form was suggested.

A Consideration of the Convulsive Toxemias of Pregnancy, Embodying the Results of Recent Important Research.—By Dr. Ross McPherson. The author stated that of all the problems with which the obstetrician had to deal there was probably none which offered more difficulty than the condition known as the toxemia of pregnancy. Not knowing the cause, we were at a loss to secure a satisfactory treatment, and this, up to the present time, had been most empirical and extremely inefficacious in its results. Toxemia of pregnancy was the name which was applied to that class of cases characterized by headache, bowel disturbance, nausea, vomiting, delirium, and coma, and usually accompanied by edema; occurring many times without previous warning or indication of its presence. The mortality, both maternal and fetal, was appalling, and the multiplicity of treatments recommended by physicians gave testimony to the worthlessness of such treatments, as of necessity the large majority had been directed toward the combatting of symptoms, and not toward relieving the cause of the disease. It had been the custom to divide the toxemias into those occurring with convulsions and those occurring without, those where convulsions were not present being spoken of as plain toxemias, and where they were as eclampsias. The condition occurred in approximately 1.7 per cent. of all labors in hospital practice and .09 of 1 per cent. of all labors in private practice. It was almost twice as common in primiparæ as in multiparæ, and was apparently proportionately more often noted in multiple pregnancies than in single ones. The maternal mortality naturally varied somewhat according to the treatment, and the figures given in the literature varied from 5 to 50 per cent., of which the latter was the more nearly correct. In the 250 cases on which this article was based the maternal mortality was, in the hospital wards, 30.8 per cent., and in the out-patient department 23 per cent., the difference between the two being explained by the fact that many of the cases in the hospital were not seen until they had been in the convulsive state for a long time, whereas those cases in the out-patient department were treated immediately. The fetal mortality was very high, varying from 33 per cent. to 50 per cent. The disease was formerly considered to be of renal origin, and as such was considered an uremia. More careful and extended observation, however, had shown that the kidney involvement was entirely secondary. The common lesions found were those of degeneration of the parenchymatous organs, notably the liver, followed by the kidney, less commonly by the spleen and pancreas. This took the form of an albuminous change known as cloudy swelling, passing on to a fatty degeneration early in the disease and later in the more aggravated forms, extending to all the tissues. In the other toxemias of the nonconvulsive type we found zonal necrosis in the liver lobules. In eclampsia, on the contrary, we usually found extensive hemorrhages in and about the portal spaces, with very little zonal necrosis. The hemorrhages were general in character, being especially marked in the brain about the corpus striatum, and in the fourth ventricle. The thyroid gland was hypertrophied and might show cystic degeneration. There was edema in many cases, hemorrhages in the serous and mucous membranes, and occasionally subcutaneous hemorrhages and jaundice. Concerning the cause of these hemorrhages, Welch had suggested that there was circulating in the blood a poison which, by causing agglutination of the red cells, formed emboli, and by solution of the endothelium of the blood vessels allowed an easy means of escape for the blood. Concerning the ordinary sources of the poison, they were generally regarded to be four in number: The foods fermentation in the intestine, cell metabolism, the fetus, and the placenta. Discussing the treatment of the convulsive toxemias of pregnancy, Dr. McPherson said it was divided into the prophylactic, operative, and curative, according to whether the patient showed symptoms of a threatened attack or whether the convulsions had actually occurred. As we did not know the exact cause of the disease, we could not do more than try to remove by means of elimination the burden from the already overloaded organs. As a prophylactic measure we should watch the patient's elimination with the utmost care, and where the normal channels were not working to their best advantage we should aid them in every possible way. Careful and frequent examinations of the urine should be made, proper at-

tention being paid to the presence of albumin, urea, indican, acetone, and diacetic acid. The nitrogen partition might be of use in cases where it could be done. This required, however, the services of a trained chemist and was, after all, of somewhat speculative value. When convulsions occurred the uterus should be emptied without delay. The means by which this should be done would vary somewhat with the experience and preference of the operator. If possible, it was desirable to have the patient in a hospital, for even under the best circumstances the cases were not likely to do well and the facilities for operation and care which the modern hospital afforded added greatly to the patient's chances for recovery. The means of delivery which might be used consisted of artificial dilatation of the cervix and rapid extraction, either by internal podalic version, forceps, craniotomy, vaginal cesarean section, or abdominal cesarean section. Of these, manual dilatation of the cervix, combined with internal podalic version or forceps, would be most often employed. Vaginal cesarean section presented a great many difficulties to the operator not skilled in vaginal work, especially if the patient be at or about term. Dr. McPherson said that in the recent report from the Rotunda Hospital of Dublin a series of cases was quoted where morphine in extremely large doses had been used in the treatment of convulsive toxemias of pregnancy with a marked reduction in mortality, the method of treatment having extended over a period of several years. No other measures were used, the patients not even being delivered with any promptitude or speed. Nitroglycerin to reduce the pulse tension was of considerable value, and the thyroid extract had lately received marked attention. Veratrum viride was used extensively throughout the South and West, but it was difficult to understand why it should be of any particular value, in spite of the fact that many men regard it as a specific. Added to the medication mentioned large irrigations of normal saline solution or instillations of the same were advised in suitable cases, and bleeding, followed by intravenous infusion or normal saline solution, hot packs, and free catharsis, might be used.

Dr. John E. Welch said that his experience with this condition was largely limited to post-mortem examinations, although most of the cases he had also seen prior to death in the Lying-in Hospital. The first question that arose was whether eclampsia and the toxemia of pregnancy were one disease. Out of sixteen cases that had come under his observation, eleven were clinically diagnosed as eclampsia, and of these seven showed the characteristic hemorrhages in the portal region or in the serous or mucous membranes, while five showed a necrosis around the central vein in one of the hepatic lobules. These were the two characteristic lesions of this condition—either hemorrhage or necrosis. Of those clinically diagnosed as the toxemia of pregnancy three showed hemorrhages and four showed central necrosis. Two other conditions were also occasionally met with, namely, one, a general autolysis, and the other, cloudy swelling. Autolysis was the term applied to the condition where the cell was very much swollen, and in which the entire cell contents appeared to have been dissolved out. In the cases showing central necrosis a few of the cells were in this condition of general autolysis. Cloudy swelling was found in two cases, with severe nephritis; possibly they were simply cases of uremia. The kidney lesion in all these cases was very similar, showing marked cloudy swelling, usually with considerable sloughing of the epithelium. The cell changes were not limited to the liver, similar changes being found in the endothelium of the blood vessels. The blood of these patients, Dr. Welch said, was usually more or less toxic; there was considerable hemolysis, with agglutination of the red cells, including the platelets. The extensive thrombi often present were usually formed by the blood platelets, with the subsequent fibrin formation. As to the source of this toxin in the blood it was difficult to say. Autopsies on three fetuses showed considerable degeneration of the liver. It was impossible to say whether the toxin was due to a diseased placenta; in some cases the placenta was apparently healthy, while in others it gave evidence of disease. Personally, Dr. Welch said, he was not prepared to assert whether eclampsia and the toxemia of pregnancy were two diseases or one and the same disease. There was no straightforward pathology for cases of eclampsia. In four of his cases there were extensive hemorrhages in the brain, two of them in the basal ganglia. One of these had convulsions and had been diagnosed as a case of eclampsia; the other case had all the symptoms typical of the toxemia of pregnancy, but showed the hemorrhagic changes in the liver and brain. In two of the cases the hemorrhage was into the pons and had ruptured into the fourth ventricle.

Dr. Charles Jewett of Brooklyn, after congratulating Dr. McPherson upon the results of his work in connection with the convulsive toxemias of pregnancy, said that even without a knowledge of the more recent results of laboratory research, the importance of which could not be overestimated, the treatment of this condition by the obstetrician in the past had been more rational than one would at first be led to assume. On general principles, the treatment had aimed to limit the production of the disease poisons and to promote elimination of those already formed. The diet was restricted and the emunctories, especially the bowels and kidneys, were stimulated. This is the treatment to-day. As an anti-eclamptic, Dr. Jewett said he had recently made some little use of hyoscine and morphine, with satisfactory results. Morphine alone he had not used, believing it would tend to deepen the coma following a convulsion. The treatment of this condition by extremely large doses of morphine, as practiced by Stroganoff and in the Rotunda Hospital in Dublin, was not new. It was advocated a number of years ago by a physician in Canandaigua in this State. As to veratrum viride, the speaker said that some years ago he reported some twenty-two cases in which this remedy had been employed, with a death rate of between 13 and 14 per cent. by eclampsia, a somewhat smaller mortality rate than prevailed at that time. Dr. Jewett said he had never seen a convulsion occur when the woman was sufficiently under the influence of this drug to hold the pulse below 60. Prompt evacuation of the uterus usually was imperative. With reference to the incisive operations vaginal cesarean section he thought was suited only to cases two or three months or more before term. At the ninth month the operation was difficult, and it involved too much traumatism, which might still further be increased by difficult extraction of the child at that time. This method was especially indicated in cases in which the cervix was rigid and immediate delivery was indicated. He had used Dührssen's incisions, laterally, with good results in term labors, as a supplementary procedure in emergency. Cesarean section, at term, he thought was better done by the abdomen. As a rule, however, the usual obstetric methods he believed were best.

Dr. Egbert H. Grandin said that with no intention of decrying or minimizing the importance of these laboratory researches in connection with the toxemias of pregnancy, he had sometimes wondered whether these finer tests were absolutely essential, and whether the general practitioner, overworked and underpaid as he was, into whose hands

the majority of the obstetrical work naturally fell, was not competent to recognize the early symptoms of this condition by the ordinary urinary tests for albumin, casts, and urea, and without ascertaining the nitrogen partition, or the presence or absence of acetone, diacetic acid, etc. Referring to the different types of the toxemia of pregnancy, Dr. Grandin said that in that type associated with severe vomiting, which was dependent on structural changes in the liver, that obstetrician would get the best results who recognized the seriousness of the condition early enough to prevent the so-called "uncontrollable vomiting of pregnancy" from becoming uncontrollable. This could perhaps be done by proper elimination and by stimulating the kidneys, and for that purpose there was nothing better than frequent lavage of the colon with hot saline solution, keeping it up for hours, if necessary. To lower the pulse, venesection might be resorted to advantageously, and when a convulsion was imminent, hyoscine hydrobromate, in doses of 1-50 grain, should be given and repeated as often as was necessary until its effects were apparent. To the use of morphine, which arrested both secretion and excretion, he was opposed. As to surgical measures, both the abdominal and vaginal cesarean section could practically be excluded, so far as the general practitioner was concerned. The purpose he had in view was to empty the uterus as rapidly as possible, and, as a rule, the best method within his reach to effect that was to make deep incisions of the cervix, where the vaginal portion was merged into the lower uterine segment, followed by manual dilatation and usually podalic version. Anything more than that along surgical lines should rarely be attempted outside of a properly equipped institution.

Dr. Frederick E. Sondern said that if the nature and origin of the toxin to which Dr. McPherson had referred could be discovered, our methods of diagnosis and probably treatment would be greatly simplified. While there were many reasons to believe that it is a hepatotoxemia, thus far no plausible theory regarding the origin of the toxin had been advanced, and in the meantime the urine, particularly, had been looked to for guides by means of which we could estimate the severity of the toxemia and determine the time beyond which it was no longer safe to leave the woman undelivered. We should not lose sight of the fact, however, Dr. Sondern said, that the changes observed in the urine were simply the result of the same toxemia that gave rise to the various pathological changes and to the clinical symptoms; that they were dependent on the same toxemia which caused the convulsions and the hyperemesis. We should also remember that the degree of acidosis indicated by the urine did not necessarily indicate the amount of the mother substance beta-oxybutyric acid circulating in the blood. Persons also varied as to the amount of poison the system would tolerate, and doubtless women varied in their susceptibility to this particular toxin as they did to other poisons. Two general errors, the speaker said, had been made in connection with this disease: First, in ignoring the urinary findings that were of use in corroborating the diagnosis of the serious stage of this condition. Second, in considering definite degrees of fault in the figures obtained on analysis as justifying definite clinical conclusions without regard to the clinical aspect of the case. His own experience with a considerable number of specimens from patients of this kind had taught him that it was either a strange coincidence or a fact, that most women who developed a toxemia of pregnancy previously gave evidences of a distinct intestinal autointoxication, as shown by a relative excess of ethereal sulphates and often by an excess of indican in the urine. This he had found to precede a toxemia of pregnancy in at least 90 per cent. of the cases, and the condition it indicated should be remedied if possible. In analyzing the urine of pregnant women if a more complete investigation cannot be made, the tests for indican and acetone should certainly not be omitted. If evidences of an acidosis were present it usually pointed to a toxemia unless explained by partial starvation. If partial starvation due to hyperemesis could be ruled out, then energetic measures should be taken to overcome the toxemia, the only symptom of which might be headaches. If, as the result of treatment, the hyperemesis and other symptoms seem to improve, while the evidences of acidosis in the urine become more pronounced, then the outlook was graver, and the presence first of an excess of urobilin and later of bile pigment in the urine should be looked for. As to the value of the nitrogen partition, we knew that in this as well as in some other toxemias the nitrogen partition was deranged, and while a knowledge of the degree of this derangement was always a valuable factor, it did not necessarily give us a certain indication for the premature emptying of the uterus. In brief, the figures obtained from the nitrogen partition should be used as corroborative evidence and not as a distinct indication. Another point referred to by the speaker was that he found in the laboratory, that the changes in the urine caused by the toxemia continued to exist for a longer or shorter time after the uterus had been emptied; this fact, and the shock attending the procedure should not be overlooked. When emptying the uterus was contemplated, the operation should be done while the patient still possessed sufficient strength to overcome the shock and the toxemia that was bound to persist for a time afterward.

Dr. I. L. Hill said that while the practitioner, up to the present, was largely dependent on the clinical symptoms in dealing with this condition, he thought that for the final solution of the problem we must look to the pathologist. Since its pathology had been elaborated, incomplete as it still was, the profession had come to assume a different attitude toward eclampsia. They did not attach so much importance to clinical treatment, the outlook in these cases depending largely upon the amount of destruction of the liver cells. In the treatment of the convulsive toxemias of pregnancy, Dr. Hill said, he had personally found veratrum viride very useful, and the same was true of morphine, even when not given in combination with hyoscine. Referring to operative measures, the speaker called attention to the difficulty and danger of attempting the rapid dilatation of a rigid cervix. Under such conditions there was very little stretching, but a great deal of tearing of the small fibers. The procedure always produced considerable injury, and not infrequently resulted in rupture of the uterus into the broad ligament. It was questionable whether it should be attempted by one who was not prepared to do a more serious operation, if the necessity arose. Venesection was an admirable measure, providing the convulsion came after delivery, but when attempted before delivery one had to face the unfortunate possibility of having a severe uterine hemorrhage afterwards further deplete the patient.

The discussion was continued by Drs. Morris and Gallant, and was then closed by Dr. McPherson.

College of Physicians of Philadelphia.

At a stated meeting held March 2 Drs. Alfred C. Wood and Augustus A. Eshner presented a communication entitled "Actinomycosis (Streptothricosis) in Man, with the Report of a Case of Pulmonary Involvement." The patient was a man, 36 years old, for many years engaged in the manipulation of furs, who presented himself with symptoms of chronic pleurisy with effusion. He was tapped on several occasions, with the evacuation of varying amounts of turbid serum, and eventually portions of rib were excised, with the discharge of grumous pus. The diagnosis remained in doubt until typical granules of the actinomyces were discovered in the discharge,

but the patient did not long survive. Dr. JOHN H. W. RHEIN presented a communication entitled "Meningitis and Disease of the Radicular Nerves in Tabes Dorsalis." He reported the results of a histologic study of a considerable number of specimens from cases of tabes and syphilis of the central nervous system, showing that changes in the radicular nerves of the cord are not constant in cases of tabes and that meningitis is not constant at all stages of the disease. Like conditions were present in cases of tabes complicated by syphilis, and he considered such changes as episodic and not an essential feature of the disease of the posterior columns. Drs. DAVID RIESMAN and FRANCIS T. STEWART presented a communication entitled "Obliterative Gastritis (Plastic Linitis)." They reported a case of a man presenting symptoms of disease of the stomach of obscure character attended with persistent vomiting and marked emaciation, together with the presence of a tumor-like mass in the abdomen. Operation disclosed a contracted stomach, with enormously thickened walls and obstruction at the pylorus. Pyloroplasty was performed and the patient was greatly relieved, gaining in weight, although vomiting persisted in less degree than previously. Histological examination disclosed the presence of marked submucous hyperplasia, but *Treponema pallidum* could not be discovered in the tissues, although there was a history of syphilis in the case. Dr. EDWARD H. GOODMAN presented a communication entitled "Historical Note on Ludwig's Angle or the Angle of Louis (Angulum Ludovici)." He pointed out that the angulation observed in some cases of pulmonary tuberculosis between the junction of the manubrium and gladiolus of the sternum was named after the great French clincian, Louis, but careful investigation failed to disclose any reference to the sign in the writings of this author. In his description of emphysema of the lungs, however, Louis makes reference to a prominence of the chest between the clavicle and the fourth rib on one or both sides as distinctive of this affection. Dr. ALFRED STENGEL reported "A Case of Actinomycosis of the Cheek with Recovery." The patient was a girl who suffered an injury of the cheek at the hands of a dentist in the process of filling carious teeth. The injured part became swollen and indurated. An incision was made through the mucous membrane, but nothing characteristic was discovered in the discharge. At a later period it became necessary to make a further incision, and at this time examination of the disharge disclosed the presence of characteristic granules. Potassium iodide was administered in doses up to 60 grains a day, without noteworthy improvement, but, later, local applications of tincture of iodine were made in addition, and the patient eventually recovered and is still alive after an interval of six years.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF WASHINGTON.

January, 1910.

ANATOMY.

1. Name muscles attached to the great trochanter of the femur.
2. Into what two classes are muscles divided? Describe each.
3. Describe Poupart's ligament; name anatomical relations and what passes beneath it.
4. Name the twelve pairs of cranial nerves.
5. Name bones articulating with humerus.
6. Describe diaphragm, its principal openings and nerve supply.
7. What forms the internal hamstring?
8. What constitutes the brachial plexus?
9. Name the cranial nerve having greatest distribution.
10. Locate and describe Peyer's glands.
11. Name the nerves of the eyeball.
12. Describe the spinal column, special and peculiar vertebra.

PHYSIOLOGY.

1. Describe how nature stops the flow of blood from a wound, and tell how you would assist her.
2. What is meant by "physiological leucocytosis," and under what conditions found?
3. What is the difference between lymph and serum? Is the former a product of the lymphatic glands?
4. Name at least four functions of the liver.
5. Explain anabolism and katabolism.
6. How can we afford the greatest voluntary assistance to the entrance of venous blood into the heart?
7. Give the nervous control of the heart.
8. What do you understand by "phagocytosis"?
9. Describe the pancreatic juice, giving the ferments and their specific action.
10. What is food? Classify and give its function.
11. Compare the path followed by a motor nerve impulse passing to a skeletal muscle with that of an impulse which reaches an involuntary muscle.
12. Give various causes for the flow of saliva.

CHEMISTRY AND TOXICOLOGY.

Answer ten questions only.

1. Give two tests for albumin in urine. What is the specific gravity of normal urine, and how is it determined?
2. How would you test for sugar in urine that is strongly acid? Which kind of sugar is reduced in the test?
3. Give methods of detecting bile in urine.
4. What are the active principles in saliva, gastric juice, pancreatic juice? What is their chemical function in digestive economy?
5. What substances may be present in a good drinking water? What substances would you consider harmful or undesirable?
6. Give the chemical composition of pure air. In respiration, what is inhaled and what is exhaled? How do the gases enter and leave the body?
7. What is the poison in (*a*) paris green? (*b*) in "rough on rats"? Differentiate between poisoning by arsenic and phosphorus.
8. Give antidotes for poisoning by belladonna, corrosive sublimate, and carbolic acid.
9. What are ptomains? When would you suspect ptomain poisoning? What is the cause of milk and ice cream poisoning?
10. What parts of the body would you prepare for the toxicological chemist, and how?
11. What is the poison in most headache powders? Its effect? Antidote?
12. A patient has died in convulsions; poison is suspected. What poisons might be looked for?

HISTOLOGY.

Answer ten questions only.

1. Describe the blood.
2. Give the histological structure of a nerve.
3. Describe cartilage and name varieties.
4. Differentiate the histological structure of arteries and veins.
5. Name and describe the membranes of the brain and give function of each.
6. Differentiate white fibrous tissue and yellow elastic tissue as to structure and function.
7. Describe a red blood corpuscle. Where do they have their origin?
8. Give the histological structure of the human skin.
9. Describe normal urine.
10. Give the histological structure of the walls of the stomach.
11. Describe the microscopic appearance of the liver in a healthy adult.
12. Name three types of epithelium and give location of each.

GENERAL DIAGNOSIS.

1. What is the normal position of the apex beat, and how is it affected by disease of the heart? What are the two kinds of cardiac murmurs? Name and define the areas over which they are best heard.
2. Define acute anterior poliomyelitis. Give pathology, symptoms, prognosis, and differential diagnosis.
3. Describe a fracture of the upper third of the humerus in a patient at fifteen years of age, and distinguish from other conditions in this region following trauma.
4. Give the differential diagnosis between iritis, corneal

ulcer, and conjunctivitis. Give the causes and sequelæ of each.

5. Give the symptomatology of tuberculosis of the kidney and the differential diagnosis between it and renal calculus, hydronephrosis, and pyelitis.

6. Give definition of acute osteomyelitis, the pathology, symptomatology, and differential diagnosis between it and acute rheumatism.

7. Give the symptoms and physical signs of bronchopneumonia and differentiate from lobar pneumonia and bronchitis.

8. Name the varieties and give the signs of dislocation of the head of the radius, and exclude other conditions about the elbow following an injury.

9. In syphilis, when is the cerebral involvement usually manifested? What structures are involved? Give the symptoms, sequelæ, and differential diagnosis.

10. Give the pathology and symptoms of intussusception, and differentiate this condition from volvulus, fecal impaction, appendicitis, and mesenteric thrombosis.

11. Give the period of incubation, describe the rash of scarlet fever, and differentiate from other eruptions simulating it. What are the most frequent complications and sequelæ of this disease?

12. Trichiniasis; describe the parasite, its habitat, and mode of infection. Give the symptoms and prophylaxis.

PATHOLOGY.

Answer ten questions only.

1. Describe the macroscopic and microscopic appearance of an epithelioma of the lip.

2. Describe the pathological changes in a case of cerebrospinal meningitis.

3. Name varieties of casts found in the urine, and give their clinical significance.

4. Define anemia, hyperemia, leukemia, and leukopenia.

5. What pathological changes usually take place in chronic inflammation of the bones?

6. What is (*a*)an embolus, (*b*) a thrombus, (*c*) an infarct?

7. Describe the formation of an acute abscess.

8. Differentiate sarcoma and carcinoma, and give diagnostic pathology of each.

9. State by what two methods the tubercle bacillus produces its specific tissue changes.

10. Give pathology of locomotor ataxia.

11. Name the intestinal lesions of typhoid fever, and give pathology of each.

12. Name stages of syphilis, and give their pathology.

OBSTETRICS.

1. Name and define the five principal diameters of the fetal head. Tell which is the longest and which plane in a normal labor is in relation to the successive planes of the pelvis.

2. What is meant by placenta prævia? What are the types, symptoms, physical signs, and dangers?

3. What is eclampsia? Give its etiology, symptomatology (both prodromal and during the attack), and diagnosis.

4. Define the term puerperium. Name and give the causes of the principal pathologic processes that may affect the mother during that period.

5. Name and give the causes of the principal disease, both hereditary and acquired, which may affect the newborn infant.

6. Give the mode of onset and symptoms of a puerperal infection, and discuss the prognosis.

7. How would you diagnose a left sacroposterior position, and what are the dangers of the delivery?

8. What do you mean by the mechanism of the second stage of labor? What are the various movements in a normal labor? Discuss each briefly.

9. Describe the changes in nutrition, digestion, urine, and nervous system which may occur in a normal pregnancy.

10. From what conditions would you have to diagnose a pregnancy at the end of the third month? Give the symptoms and signs of pregnancy at that time, and give the distinguishing features in each case.

11. Define presentation, position, and posture. Give each in normal labor, and tell what causes are most liable to modify each and so cause an abnormal labor.

12. Define menstruation, ovulation, placenta, chorion, amnion, allantois, decidua vera, meconium, caput succedaneum, cephalhæmatoma.

GYNECOLOGY.

1. Name the contents of the female pelvis; their normal positions and relations.

2. Give anatomy of floor of pelvis and the results of its destruction.

3. State the uterine displacements most commonly met. Give their chief clinical symptoms.

4. Give some of the most common causes of menorrhagia and metrorrhagia—local, constitutional, and vascular.

5. Gonorrheal infection in the female, acute and latent; give parts involved, symptoms objective and subjective, and other diagnostic methods; give dangers immediate and remote of the disease.

6. Give hygienic regulations for girl at puberty.

7. Give etiology of sterility in the female.

8. Give causes of pruritus vulvæ.

9. Differentiate extrauterine pregnancy from appendicitis and salpingitis.

10. Give effects on general health by fibroid tumors; their subjective symptoms, prognosis, and degenerative changes that may occur.

11. Give diagnostic signs and symptoms of cancer of the fundus of the uterus, and from what is it to be differentiated?

12. From what is a large ovarian cyst to be differentiated, and how done?

HYGIENE.

Answer ten questions only.

1. Give a few important rules for the care and control of tuberculosis.

2. What are the methods of transmission of the more important infectious and contagious diseases? Give illustrations of each.

3. What are the most common sources of infection in diphtheria, and what hygienic precautions should be employed?

4. What measures would you employ for the prevention of the spread of contagious diseases?

5. Differentiate between endemic and epidemic diseases.

6. Through what media is the typhoid infection usually communicated?

7. What gases are most efficient as disinfectants?

8. How would you disinfect (1) rooms, (2) clothing, (3) hands, (4) urine and feces, water closets, etc.?

9. What diseases are incident to school life, and how prevented?

10. What are (*a*) toxins, (*b*) antitoxins?

11. If a chemical analysis of water revealed the presence of nitrites and nitrates, would this condemn it for drinking? If so, why?

12. Mention the principal diseases that should be quarantined? And how would you determine the length of time in each?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF WASHINGTON.

January, 1910.

ANATOMY.

1. Gluteus medius, gluteus minimus, pyriformis, obturator externus, obturator internus, superior gemellus, inferior gemellus.

2. Striated, unstriated, and cardiac. See Gray's "Anatomy" (1908), page 363.

3. See Cunningham's "Anatomy" (1909), page 422; or, Gray's "Anatomy" (1908), page 438.

4. The twelve pairs of cranial nerves are: (1) Olfactory. (2) Optic. (3 Motor oculi. (4) Trochlear or Pathetic. (5) Trifacial. (6) Abducens. (7) Facial. (8) Auditory (9) Glossopharyngeal. (10) Pneumogastric or Vagus. (11) Spinal Accessory. (12) Hypoglossal.

5. Scapula, ulna, and radius.

6. The *diaphragm* is a musculofibrous septum which divides the thoracic from the abdominal cavity; it is fan-shaped; the broad, elliptical portion is horizontal, and the crura are vertical. It is attached to the ensiform, to the internal surfaces of the lower six costal cartilages, to bodies and intervertebral substances of first, second, and third lumber vertebræ. Its *openings* are: (1) The aortic, (2) the esophageal, (3) the opening for the vena cava, (4) the right crural, (5) the left crural. *Nerve supply:* Phrenic, lower intercostal, and sympathetic.

7. The tendons of the Semimembranosus, Semitendinosus, Gracilis, and Sartorius.

8. The *brachial plexus* is formed by the union and subsequent division of the anterior divisions of the fifth, sixth, seventh, and eighth cervical and the first dorsal nerves.

The union of the fifth and sixth makes the upper trunk; the seventh forms the middle trunk, and the eighth cervical and first dorsal make the lower trunk. Each of these trunks is divided into an anterior and a posterior branch. The anterior branches, from the upper and middle trunks, make the upper or outer cord of the plexus; the anterior branch of the lower trunk becomes the lower or inner cord; the three posterior branches unite to form the posterior or middle cord. The plexus lies between the Scalenus anticus and medius.

9. The tenth, or pneumogastric.

10. See Cunningham's "Anatomy" (1909), page 1064; or, Gray's "Anatomy" (1908), page 1304.

11. *Sensory,* from branches of the first division of the fifth cranial nerves; *motor,* from third, fourth, and sixth cranial nerves.

12. See Cunningham's "Anatomy" (1909), pages 88, 75, 79, etc.; or, Gray's "Anatomy" (1908), pages 67, 50, etc.

PHYSIOLOGY.

1. Nature's way of stopping the flow of blood from a wound is by the coagulation of the blood. This may be helped by anything that aids coagulation, such as styptics or the application of gauze, bandages, etc.

2. *Physiological leucocytosis* is an increase in the number of the white blood corpuscles occurring under normal or physiological conditions, such as: Digestion, exercise, after a cold bath, or during pregnancy.

3. *Lymph* is diluted blood without the red corpuscles; *serum* is practically blood plasma, with the exception of the substances which enter into the formation of fibrin. Lymph is not a product of the lymphatic glands.

4. The *functions of the liver* are: (1) The secretion of bile; (2) the formation of glycogen; (3) the formation of urea and uric acid; (4) the manufacture of heat, and (5) the conversion of poisonous and harmful into inert material.

5. *Metabolism* is the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Assimilative, or constructive (*anabolism*), and (2) destructive (*katabolism*).

6. By taking deep inspirations.

7. The *nerves which control the heart* are: (1) The pneumogastric nerve, which slows or inhibits the heart beats; (2) the sympathetic nerves, which accelerate or augment the beats; and (3) the intrinsic cardiac ganglia, which enable the heart to continue beating for some time after it is removed from the body.

8. *Phagocytosis* is the faculty of certain cells (notably the mononuclear and polynuclear leucocytes) to take up and destroy bacteria.

9. The *pancreatic juice* is a colorless, viscid, odorless, salty fluid, alkaline in reaction, and of a specific gravity of about 1030. *Composition:* Water and solids, the latter consisting of three enzymes (trypsin, amylopsin, and steapsin), proteid material, soaps, fats, lecithin, and inorganic salts (carbonate of sodium, chloride of sodium, and phosphates of sodium, calcium, and magnesium).

Ferments: (1) *trypsin,* which changes proteids into proteoses and peptones, and afterward decomposes them into leucin and tyrosin; (2) *amylopsin,* which converts starch into maltose; (3) *steapsin,* which emulsifies and saponifies fats; and (4) a milk-curdling ferment. All of these act in an alkaline medium only.

10. *Food* is material which, after being taken into the body, is capable of building up the body, of repairing tissue waste, and of supplying heat and energy. *Foods are classified* as:

I. Inorganic. { Water. / Salts.

II. Organic.... { Nitrogenous—Proteids. / Non-Nitrogenous. { Carbohydrates. / Fats.

Function of proteids: Formation and repair of tissues and fluids of the body, regulation of the absorption and utilization of oxygen, formation of fats and carbohydrates, production of energy. *Function of carbohydrates:* Production of heat and energy, and formation of fats. *Function of fats:* Supply of heat and energy, supply of fatty tissues, nutrition of nervous system. *Function of salts:* Support of bony skeleton, supply of HCl for digestion, regulation of nutrition and energy. *Function of water:* It enters into the composition of all the tissues and fluids of the body, it moistens the surfaces and membranes of the body, it keeps the fluids of the body at their proper degree of dilution, it removes waste matters, distributes and regulate body heat.

11. To a *skeletal* muscle the motor nerve impulses start in the cortex cerebri, and pass through the corona radiata, internal capsule, crus, pons, medulla, crossed and direct pyramidal columns to motor cells of anterior horn of spinal column, thence through nerve root and motor nerve to muscle. To *involuntary muscle:* The efferent fibers of the sympathetic nervous system arise in the intermediolateral column of gray cells. They pass out by the anterior root from the spinal chord. From here they go by a white ramus to a sympathetic ganglion. From the sympathetic ganglion they may pass in two directions: (1) they may form synapses about these cells and from these cells new axons may arise and pass outwards in the visceral nerves, or back through the gray ramus connected to the ganglion, into the spinal or somatic nerve to the blood-vessels as vasomotor nerves, or sweatglands as secretory nerves, or to hairs as pilomotor nerves; (2) or they may pass through the ganglion on to one situated more towards the periphery, in which they form synapses and are continued onward by new axons."

12. *Causes of flow of saliva:* The taste, sight, or smell of food; the hearing of sounds associated with the preparaton of food, various drugs (sialagogues), section of chorda tympani, or stimulation of its peripheral end when divided; section of sympathetic nerves supplying the salivary glands, or stimulation of the peripheral end, when divided; the thought of savory food; the feeling of nausea which precedes vomiting.

CHEMISTRY AND TOXICOLOGY.

1. TWO TESTS FOR THE DETECTION OF ALBUMIN IN THE URINE: "The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent it is to be treated with a few drops of magnesia mixture and again filtered." I.—*The heat test:* "The reaction is first observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3."

II.—*Heller's modification of the nitric acid test:* "Place in a test-tube a layer of HNO_3 about 2 c. in thickness; then with a pipette, carefully float upon the surface of this a layer of the urine in such a manner that the liquids do not mix. If albumin be present, a cloudy ring appears *at* the point of junction of the two layers, the borders of the cloud being sharply defined. A cloudy ring may be formed by the presence of an excess of urates, but in this case it is not *at,* but *above,* the point of junction of the layers, and its upper border is not sharply defined, but fades off gradually." (Witthaus' *Essentials of Chemistry.*)

The specific gravity is about 1015 to 1025, and is determined by means of a urinometer.

2. *Boettger's test for sugar:* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color. The kind of sugar reduced is glucose.

3. *Test for bile pigment in the urine:* Put 3 c.c. HNO_3 in a test-tube; add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquid, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

4.

SECRETIONS	ACTIVE PRINCIPLES	FUNCTION.
Saliva.....	Ptyalin.	Changes starches into dextrin and sugar.
Gastric juice...	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
Pancreatic juice	Trypsin.	Changes proteids into proteoses and peptones, and afterward decomposes them into leucin and tyrosin; in an alkaline medium.
	Amylopsin..	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.

5. Good drinking water may contain the following in very small amounts: Free ammonia, albuminoid ammonia, nitrogen as nitrates, nitrogen as nitrites, and chlorine. Harmful or undesirable substances would include all the above in larger quantities, and the following: Sewage, leaves, surface washings, manufacturing refuse, lead, other metals, leakage from gas pipes, insects, fungi, bacteria, entozoa.

6.

	INSPIRED AIR	EXPIRED AIR.
Oxygen	21 per cent.	16.6 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide...	0.04 per cent.	4.4 per cent.
Other gases.....	Rare.	Often present.
Watery vapor....	Variable.	Saturated.
Temperature	Variable.	That of body.
Volume	Varies.	Diminished.
Bacteria	Always present.	None.
Dust	Always present.	None.

The gases enter and leave the body by the process of diffusion, or differences in pressure in the alveoli of the lungs.

7. The poison in *Paris green* is arsenic; in *Rough on Rats,* is phosphorus. *Arsenic:* The symptoms usually begin in from twenty to forty-five minutes; nausea and faintness; violent, burning pain in the stomach, which becomes more and more intense, and increases on pressure. Persistent and distressing vomiting of matters, sometimes brown or gray, or streaked with blood, or green (Paris green); purging; more or less severe cramps in the lower extremities.

Phosphorus: Eructation of gas having the odor of garlic. The mouth, when observed in the dark, is frequently faintly luminous (phosphorescent). After several hours, pain in the throat, a sense of heat in the epigastrium, nausea, and vomiting. The vomited matters are sometimes bloody, and frequently luminous when agitated in the dark. The abdomen is tender, and there are diarrhea and colicky pains. After one or two days these symptoms cease, there remaining only pain in the back and limbs and a feeble pulse. Death sometimes occurs suddenly in from two to four days. Usually about the fourth day the patient becomes jaundiced, suffers from headache, insomnia, and retention of urine, rapidly becomes delirious and comatose, and dies. (From Witthaus' *Essentials of Chemistry and Toxicology.*)

8. Antidote for *belladonna,* none; pilocarpine and morphine are often given. For *corrosive sublimate,* milk or white of egg in moderate quantity, followed by an emetic. For *carbolic acid,* a soluble sulphate, such as sodium or magnesium sulphate, or alcohol.

9. *Ptomains* are basic nitrogenous compounds, produced from protein material by the bacteria which cause putrefaction. They are found in protein foods which have partly undergone decomposition. *Ptomain poisoning. Symptoms:* Chilliness, headache, vertigo, muscular twitchings, hallucinations, imperfect vision, weak and rapid pulse, nausea, vomiting, diarrhea, cyanosis, early dyspnea, often subnormal temperature, and occasionally cutaneous eruptions. The cause of milk and ice-cream poisoning is tyrotoxicon.

10. In case of suspected homicidal poisoning, the following parts of the cadaver should be preserved: "The alimentary canal from the cardia to the middle of the rectum, *unopened,* and the contents enclosed by ligatures at the esophagus, duodenum, and lower end of gut; the liver, including the gall-bladder; one kidney; the spleen; a piece of muscular tissue from the leg; the brain, and any urine which may remain in the bladder.

"They are to be placed in *clean* and *new* glass jars, closed with glass or cork covers or stoppers. Jars with metallic caps should never be used. Tapes or cords should be tied about the jar and cap, to which they should be attached by sealing wax bearing impressions of a seal, in such a manner that access can only be had to the interior after breaking the seals or cutting the tapes or cords. Great care must be exercised that no sealing wax can get into the jars. Each portion should be placed in a jar by itself." (Witthaus' *Essentials of Chemistry.*)

11. ACETANILIDE. *Effect:* Chilliness, cold sweat; nausea; pulse is soft, slow, and feeble; respirations slow and shallow. *Treatment:* Lavage, diffusible stimulants, application of heat, coffee or strychnine, inhalation of oxygen, or saline infusion.

12. Convulsions occur in poisoning by: Strychnine and picrotoxin.

HISTOLOGY.

1. The blood is a fluid somewhat viscid, red, specific gravity from 1055 to 1062, alkaline reaction, saltish taste, characteristic odor, variable temperature (average about 100° F.). The *constituents of the blood* are plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteids, fat, and inorganic salts). The *white corpuscles* consist of water and solids (proteid, leuconuclein, lecithin, histon, etc.). There are also *platelets,* which are very small, colorless, irregular shaped bodies, about one-fourth the size of the red corpuscle.

2. See Cunningham's "Anatomy" (1909), page 444; or, Gray's "Anatomy" (1908), page 819.

3. *Cartilage* is a form of connective tissue; it is firm and elastic; opaque, and of a bluish color. The varieties are: (1) *Hyaline,* in which the cells are relatively few and are imbedded in a quantity of ground substance. (2) *White fibrocartilage,* in which the ground substance contains bundles or layers of white fibers, between which are encapsulated cells. (3) *Yellow fibrocartilage,* in which the ground substance contains a network of yellow, elastic fibers, and the cartilage cells are in the meshes of this network.

4. See Cunningham's "Anatomy" (1909), page 781; or, Gray's "Anatomy" (1908), page 586.

5. See Cunningham's "Anatomy" (1909), page 597; or, Gray's "Anatomy" (1908), page 972.

6. The *function of the dura* is protection: It forms the internal periosteum of the skull; it forms three partitions for the support of the parts of the brain; it forms sinuses or venous channels for the return of the blood from the brain, and it forms sheaths for the nerves as they leave the skull. The function of the *arachnoid* is lymph supply; of the *pia,* blood supply and nutrition.

7. The *red blood corpuscles* are biconcave discs, about 1-3200 of an inch in diameter; they are nonnucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They are elastic and soft, and their shape is changed by pressure, but is promptly regained on the removal of the pressure. Their color is yellowish. They contain hemoglobin. They originate in the marrow of the long bones.

8. See Cunningham's "Anatomy" (1909), page 772; or, Gray's "Anatomy" (1908), page 1190.

9. *Normal urine* is a straw- or amber-colored fluid, with specific gravity from about 1015 to 1025; its chemical reaction is acid. The normal constituents are: Water urea, uric acid, urates, hippuric acid, kreatin, kreatinin, xanthin, hypoxanthin, sulphates, chlorides, and phosphates of sodium and potassium; phosphates of magnesium and calcium, nitrogen and carbon dioxide. The average quantity voided in twenty-four hours is about fifty ounces.

10. See Cunningham's "Anatomy" (1909), page 1058; or, Gray's "Anatomy" (1908), page 1281.

11. See Cunningham's "Anatomy" (1909), page 1121; or, Gray's "Anatomy" (1908), page 1345.

12. (1) Columnar epithelium; in stomach, intestines, and ducts of most secreting glands. (2) Cubical epithelium; in thyroid, testis, and some of the glands. (3) Ciliated epithelium; in upper air passages, Fallopian tubes, ventricles of brain, Central canal of spinal cord, vasa efferentia, and tail of spermatozoa.

GENERAL DIAGNOSIS.

1. The apex beat is normally in the fifth left intercostal space, about three inches to the left of the midsternal line. It may be displaced (upward, downward, to left, to right; the impulse may be increased, weakened, or absent; the frequently may be increased or decreased; the extent may vary). The two kinds of cardiac murmurs are: (1) Hemic, and (2) Organic. The former is heard best over the base: the latter, generally over the apex or sternum, sometimes at base (the exact location varying with the valve affected).

2. See French's "Practice" (1907), page 1034; or, Osler's "Practice" (1909), page 914.

3. See Rose and Carless' "Surgery" (1908), page 5502; or, Da Costa's "Surgery" (1908), page 486.

4.

CONJUNCTIVITIS	IRITIS
1. No change in iris.	1. Discolored and altered iris.
2. Pupil normal.	2. Pupil small, gray, sluggish, irregular after use of atropine.
3. Anterior chamber normal.	3. Exudation in anterior chamber.
4. Conjunctival injection, coarse meshes, most pronounced in fornix and fading toward the cornea.	4. Ciliary (circumcorneal) injection; pink zone of fine vessels surrounding cornea and fading toward fornix.

CONJUNCTIVITIS	IRITIS
5. Mucous or mucopurulent secretion.	5. Lacrymation, but no secretion.
6. Discomfort, but no real pain.	6. Pain, worse at night.
7. Conjunctiva reddened and opaque.	7. Conjunctiva usually transparent.
8. No interference with vision.	8. Vision diminished in acuteness.

CONJUNCTIVITIS. *Causes:* Foreign body, irritation, heat or cold, exposure to light, eyestrain, infection. *Sequelæ:* Scars, ulceration, perforation, staphyloma. IRITIS. *Causes:* Syphilis, gout, rheumatism, tuberculosis, diabetes, nephritis, infections, traumatism, inflammations. *Sequelæ:* Opacities, synechiæ. CORNEAL ULCER. *Causes:* Traumatism, extension of inflammation. *Diagnosis:* It is detected by oblique illumination, the ophthalmoscope, or convex lens, and by dropping fluorescin upon the cornea, the denuded area being colored green. Pain, photophobia, lacrimation, swelling of the lids and conjunctiva, and destruction of tissue are symptoms. *Sequelæ:* Corneal opacities, staphyloma, perforation, adherent leukoma, atrophy of the eyeball, and prolapse of the lens and vitreous.

5. See French's "Practice" (1907), pages 383, 911, 910, and 907; or, Osler's "Practice" (1909), pages 346, 710, 707 and 704.

6. See Rose and Carless' "Surgery" (1908), page 570; or, Da Costa's "Surgery" (1908), page 440. In *acute rheumatism* there is successive involvement of many joints; the tenderness, pain, and swelling are over the joints, and not over the bones; profuse sweats are present, and the condition responds to treatment by salicylates.

7. See French's "Practice" (1907), page 672; or, Osler's "Practice" (1909), page 624.

8. See Rose and Carless' "Surgery" (1908), page 625; or, Da Costa's "Surgery" (1908), page 594.

9. See French's "Practice" (1907), page 423; or, Osler's "Practice" (1909), page 271.

10. See French's "Practice" (1907), page 799; or, Osler's "Practice" (1909), page 519; or, Rose and Carless' "Surgery" (1908), pages 1119 and 1123; or, Da Costa's "Surgery" (1908), page 837.

11. See French's "Practice" (1907), page 315; or, Osler's "Practice" (1909), page 130.

12. See French's "Practice" (1907), page 492; or, Osler's "Practice" (1909), page 39.

PATHOLOGY.

1. See Rose and Carless' "Surgery" (1908), pages 211 and 801.

2. See French's "Practice" (1907), page 141; or, Osler's "Practice" (1909), page 159.

3. *Hyaline* casts occur in all forms of nephritis, in congestion of the kidneys, in jaundice; *waxy* casts, in chronic parenchymatous nephritis; *epithelial* casts, in acute parenchymatous nephritis; *granular* casts, in chronic nephritis and in acute nephritis; *fatty* casts, in chronic parenchymatous nephritis; *blood* casts, in hemorrhagic nephritis; *pus* and *bacterial* casts, in suppurative nephritis.

4. *Anemia* denotes a condition in which there is reduction of the quantity or quality of the blood (generally used with reference to the red corpuscles). *Hyperemia* denotes excessive blood in a part. *Leukemia* is a condition in which the white blood corpuscles are increased in number, and is accompanied by pathological changes in the spleen, lymphatic glands, and bone marrow. *Leukopenia* is a condition in which the number of white blood corpuscles in the peripheral circulation is below the normal.

5. See Rose and Carless' "Surgery" (1908), page 578.

6. An *embolus* is a plug in a blood vessel brought thither by the blood current. A *thrombus* is a blood clot formed in the blood vessels during life. An *infarct* is an area of tissue in which, owing to the plugging up of an end artery or terminal artery, nutrition is prevented.

7. See Rose and Carless' "Surgery" (1908), page 627; or, Da Costa's "Surgery" (1908), page 132.

8. *Carcinoma* is apt to occur at a later age; is found in structures derived from the epiblast or hypoblast; possesses a fibrous stroma, in which are found both blood vessels and lymphatics; metastasis is by the lymphatics.

Sorcoma is apt to occur earlier; is found in structures derived from the mesoblast; there is no stroma between the cells; the blood vessels are in direct contact with the tumor cells; there are no lymphatics; metastasis is by the blood vessels.

9. Irritation and degeneration.

10. In *locomotor ataxia* the posterior columns of the spinal cord and the posterior nerve roots are involved.

The posterior columns of the spinal cord are gray and shrunken, and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus.

The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion; the spinal ganglia may be affected.

11. See French's "Practice" (1907), page 85; or, Osler's "Practice" (1909), page 65.

12. See French's "Practice" (1907), page 420; or, Osler's "Practice" (1909), page 267.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 153; or, Hirst's "Obstetrics" (1909), page 92.

2. See Williams' "Obstetrics" (1909), page 809; or, Hirst's "Obstetrics" (1909), page 572.

3. See Williams' "Obstetrics" (1909), page 524; or, Hirst's "Obstetrics" (1909), page 628.

4. See Williams' "Obstetrics" (1909), pages 332 and 851; or, Hirst's "Obstetrics" (1909), pages 347 and 644.

5. See Williams' "Obstetrics" (1909), page 599; or, Hirst's "Obstetrics" (1909), page 155.

6. See Williams' "Obstetrics" (1909), page 852; or, Hirst's "Obstetrics" (1909), page 712.

7. See Williams' "Obstetrics" (1909), page 284; or, Hirst's "Obstetrics" (1909), page 419.

8. See Williams' "Obstetrics" (1909), page 256; or, Hirst's "Obstetrics" (1909), page 396.

9. See Williams' "Obstetrics" (1909), page 173; or, Hirst's "Obstetrics" (1909), page 186.

10. See Williams' "Obstetrics" (1909), page 190; or, Hirst's "Obstetrics" (1909), page 204.

11. See Williams' "Obstetrics" (1909), pages 205 and 207; or, Hirst's "Obstetrics" (1909), page 388. *Posture* is the altitude of the fetus in the uterus.

12. *Menstruation* is a periodical disturbance in the female characterized by a bloody mucous discharge from the uterine cavity; it lasts during the period of woman's sexual activity, but is temporarily suspended during pregnancy and early lactation. *Ovulation* is the development and ripening of ovules in the ovary and their discharge therefrom. *Placenta* is an organ on the internal wall of the pregnant uterus, to which the fetus is attached by means of the umbilical cord. *Chorion* is the outermost of the three fetal membranes. *Amnion* is the innermost of the fetal membranes. *Allantois* is one of the fetal membranes, which enters into the formation of the true chorion and the placenta. *Decidua vera* is that portion of the decidua (or hypertrophied mucous membrane) which lines the uterine wall during pregnancy. *Meconium* is the greenish-black stools of the newborn infant; it consists of intestinal mucus, bile, epithelium, vernix caseosa, cholestrin, phosphates, and fat. *Caput succedaneum* is the edematous swelling developed on the presenting part of the fetus during birth. *Cephalhematoma* is a swelling occurring on the head of a newborn infant, due to subpericranial hemorrhage.

GYNECOLOGY.

1. See Cunningham's "Anatomy" (1909), page 1181, etc.; or, Gray's "Anatomy" (1908), pages 1440, 1498, etc.

2. *The pelvic floor* is composed chiefly of fascia, muscles, and connective tissue. Its superior surface is lined by peritoneum. Next below, and in close contact with the peritoneum, comes the "internal pelvic fascia." Immediately below the internal pelvic fascia are two thin muscles, viz.: (1) The *levator ani*, each half of which arises from the body and horizontal ramus of the pubes and from the arcus tendineus, and passes downward and inward to meet its fellow of the opposite side in the median line, where it is inserted into a tendinous raphe extending from the coccyx to the rectum, while some fibers pass between and to the sides of the bladder and rectum, and to the vaginal and rectal sphincters. (2) The *coccygeus*, which is a narrow, triangular slip, situated parallel with and posterior to the levator ani, closing in a little space which the latter muscle failed to cover. Below these muscles the pelvic floor is further strengthened by the *perineal fascia*. Its posterior portion consists of a single layer, while its anterior part is divisible into three layers. Within these latter layers are lodged the pudic vessels and nerves, and the superficial muscles of the perineum. These muscles are the *constrictor vaginæ*, the *sphincter ani*, and the *transversus perinei*, and to these structures must be added the integument and the

very numerous interstitial layers of elastic connective tissue, which latter weld the parts together and add strength and elasticity to the whole fabric.—(From King's *Obstetrics.*)

"*Tears of the perineum* destroy the integrity of the pelvic floor and result eventually in rectocele, cystocele, hemorrhoids, and displacements of the pelvic organs. If the tear involves the sphincter ani, incontinence also results. Lacerations of the cervix retard or check involution of the uterus and predispose to endometritis, menorrhagia, displacements, eversion of the cervical mucous membrane, cystic degeneration, and malignant disease. Deep lacerations of the vaginal vault may open into the base of the broad ligaments, and in the majority of instances genitourinary fistulas are caused by traumatisms of labor. All lacerations are immediately dangerous on account of the increased liability to sepsis, while the remote results are generally due to interference with involution or the pelvic circulation and to the destruction of the normal supports of the pelvis." (Ashton's *Gynecology.*)

3. *The common displacements of the uterus* are: Retroversion, retroflexion, anteflexion, and descent or prolapse. The following symptoms may follow displacements of the uterus: Backache, bearing-down pains, a feeling of pressure in the pelvis, constipation, hemorrhoids, frequent or painful urination, leucorrhea, menstrual disturbances, as dysmenorrhea or menorrhagia, sterility; there may also be *general symptoms,* as headache, indigestion, nausea, anorexia, neurasthenia, and general malaise.

4. Common Causes of Menorrhagia. *Constitutional:* Purpura, scorbutus, hemophilia, hepatic cirrhosis, over indulgence in food and alcoholic drinks. *Local and Vascular:* Uterine congestion and displacement, endometritis, subinvolution, fibroids, and other tumors. Common Causes of Metrorrhagia. *Constitutional:* None. *Local and Vascular:* Disease of uterus or appendages, polyps, extrauterine gestation, the hemorrhages in connection with pregnancy.

5. *Parts involved* are: Vagina, vulva, and urethra; uterus, tubes, ovaries, peritonenn; rectum. *Diagnosis* is made by finding the gonococcus characteristically grouped in the cells of the secretion. *Symptoms* are: Pain, discharge, painful urination, tenderness, redness, inflammation of parts affected. *Dangers:* Spread of the disease to adjoining parts or tissues, sterility, peritonitis, blindness, and spread of the gonorrhea to others.

6. *Hygiene of Puberty:* Constipation must be remedied; diet must be nutritious but simple; frequent rest, moderate amusements, and adequate exercise are necessary; the girl should be instructed with regard to menstruation and the menstrual periods; overwork at school, and nervous excitability, late hours, and much company should be avoided; books, amusements, and associates should be carefully selected.

7. *Etiology of Sterility in the Female:* Gonorrhea, absence or errors in development of any part of the genital tract, malformations of genitals, fistulæ, lacerations, obesity, alcoholism, pelvic inflammations, dyspareunia, inflammations of uterus, tubes, or ovaries, elongated cervix.

8. *Pruritus vulvæ* may be *caused by:* Parasites; diseases of the vulva, as inflammation, edema, vegetations, congestion; irritating discharges: lack of cleanliness; diabetic urine; it may also be of nervous origin, or idiopathic.

9. In *extrauterine pregnancy,* there will be signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane or shreds, softening of the cervix, enlargement of the uterus, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden, excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage. In *appendicitis,* there are no signs of pregnancy, there are sudden pain and tenderness in the right iliac fossa, rigidity of right rectus muscle, fever, nausea, vomiting, constipation, no history of menstrual irregularities. In *salpingitis,* the tubes are inflamed usually secondary to inflammation of uterus or to infection (either gonorrheal or puerperal), backache, pain in lower abdomen, history of menstrual irregularity, leucorrhea, tube is enlarged and tender.

10. Fibroids. *General effect:* Health deteriorates from the hemorrhage, pain, leucorrhea, and pressure on neighboring organs; anemia, constipation, loss of weight, edema, and hepatic troubles may ensue. *Symptoms:* Hemorrhage, leucorrhea, pain, vesical symptoms, hemorrhoids, constipation, and enlargement of abdomen. *Prognosis:* Variable: fibroids *may* cease to trouble at the menopause; but they may also degenerate, and they certainly cause much invalidism. The prognosis is better after early operation. *Degenerative changes:* Fatty mucoid, and cystic degeneration; calcification; septic infection; malignant changes.

11. *Cancer of fundus of uterus* is diagnosed by the presence of tumor, cachexia, hemorrhage, pain, and offensive discharge; microscopic examination big aid in the diagnosis. It is to be *differentiated* from: Polypi, fibroids, retained placenta, and chronic endometritis.

12. Large ovarian cyst may be differentiated from: Pregnancy, ascites, and possibly uterine tumors. *Pregnancy* gives history and signs of the condition.

ASCITES	OVARIAN CYST
1. Previous history of visceral disease.	1. No such history.
2. Enlargement comparatively sudden.	2. Gradual.
3. Face puffy; color waxy; early anemia.	3. Facies ovariana. Anemia absent, or later.
4. Patient on back, enlargement symmetrical; flat in front.	4. Asymmetrical until tumor is quite large; prominent in front.
5. Sitting up, abdomen bulges below.	5. No appreciable change.
6. Navel prominent and thinned.	6. Navel usually unchanged.
7. Fluctuation decidedly clear, diffuse throughout abdomen, but avoids highest parts in all positions, and always has a hydrostatic level.	7. Less clear; limited to cyst; not modified by change of position. No hydrostatic level.
8. Intestines float on top of fluid; hence percussion gives clear tympanitic note over the highest parts of abdominal cavity, and dulness in lowest parts for all positions—*i.e.* areas of resonance and dullness change with position.	8. No change in areas of dullness and resonance with change of position. Dullness over cyst. Clear resonant note in all parts beyond cyst limits, *i.e.* in flanks and toward the diaphragm.
9. Vaginal touch detects fluctuation, bulging into vagina.	9. Vaginal fluctuation less clear or absent.
10. Uterus in prolapsed location, but position unchanged. Size and mobility unchanged.	10. Uterus displaced forward or backward, or laterally by pressure of cyst.
11. Hydragogues and diuretics temporarily remove the fluid.	11. Medicines have no effect.
12. Fluid light straw color and thin. Coagulates spontaneously.	12. Fluid light or dark and of varying consistency; albuminous, but does not coagulate spontaneously; may contain colloid matter.

—(From Dudley's *Gynecology.*)

HYGIENE.

1. "The preventive measures which may be taken to reduce tuberculosis may be summarized as follows: (1) The compulsory notification of phthisis. (2) The removal of those conditions of domicile and of occupation which are known to promote the incidence of the disease, including the regulation of certain dusty trades. (3) The diffusion of knowledge (by medical men, leaflets, etc.) regarding the nature and modes of spread of the disease, and the precautions which should be taken in order to prevent its extension. (4) The testing of sputum and other suspected discharges, and of milk, meat, etc., supposed to be tuberculous—reports to be furnished free of charge. (5) Local authorities to undertake, without charge, the disinfection of houses recently occupied by phthisical persons. (6) The establishment of sanatoria and isolation accommodation for the cure of phthisical patients, and the isolation of those who are a distinct source of danger to fellow lodgers or workers. (7) The enforcement of measures against spitting in public conveyances and in places of public resort. (8) The efficient sanitary supervision of dairy farms, dairies, and milkshops. The periodical veterinary inspection and testing (by tuberculin) of milch cows, and the slaughter of tuberculous animals. The prohibition of the sale of milk of cows affected with tuberculosis. (9) The proper inspection of meat in public abattoirs, and the adoption of due precautions for the control of imported meat and milk." (Parkes' *Practical Hygiene.*)

2. *Disease may be transmitted by:* (1) *Air,* as tuberculosis; (2) *Food,* as tuberculosis; (3) *Insects,* as malaria, yellow fever; (4) *Milk,* as typhoid; (5) *Fomites,* as measles, scarlet fever; (6) *Contact,* as syphilis, gonorrhea; (7) *Wounds,* as tetanus.

3. Diphtheria is conveyed through the air, or by the mouth, and occasionally through wounds. *Hygienic precautions* should include isolation of the patient, strict antiseptic precautions on behalf of all who come in contact with the patient, and fumigation with sulphur or formaldehyde.

4. Isolation; quarantine; asepsis and antisepsis; common sense; cooperation with health boards; vaccination, antitoxin or other similar prophylactic.

5. *Endemic* disease is one found in a given locality more or less constantly. *Epidemic* disease is one which affects a very large part or the whole of a certain community.

6. Food, fingers, flies, milk, water, and "typhoid carriers."

7. Formaldehyde and sulphur dioxide.

8. For *disinfection of:* (1) *Rooms,* use formaldehyde gas; (2) *Clothing,* use solution of phenol (5 per cent.) for an hour, then boil for an hour; (3) *Hands,* wash in soap and water, and immerse in cresol or carbolic acid solution; (4) *Urine and feces,* etc., should be passed into vessels containing dilute solution of formalin. *Water closets,* dilute formalin solution.

9. *Diseases incident to school life:* Measles, scarlet fever, chicken pox, mumps, diphtheria, adenoids, ringworm, pediculi, myopia, trachoma, strabismus, smallpox, spinal curvature. For *prevention* see index in French's or Osler's "Practice."

10. *Toxins* are harmful or poisonous products of bacteria. *Antitoxins* are substances formed in the body, of a protective character, and capable of rendering inert the poisonous products of bacteria.

11. *Nitrates* are generally due to the oxidation of organic matter of animal origin. *Nitrites* generally indicate sewage contamination. The presence of nitrites should condemn the water; so should a marked amount of nitrates.

12. *Quarantinable diseases:* Cholera, yellow fever, smallpox, plague, typhus, leprosy, diphtheria, scarlet fever, measles, mumps, chicken pox, erysipelas. For *length of time,* see index in French's or Osler's "Practice."

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	June —
Arizona*	Ancil Martin, Phoenix	Phoenix	April 4
Arkansas	F. T. Murphy, Brinkley	Little Rock	May 10
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	April 5
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	April 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July 12
Delaware	J. H. Wilson, Dover	Dover	June 21
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington	April 12
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	April 4
Georgia	E. R. Anthony, Griffin	Atlanta	April —

VISCERAL SARCOMATA: CASES OF SARCOMA OF THE STOMACH, HEART, MEDIASTINUM, ETC.*

BY W. GILMAN THOMPSON, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE.

THE inoperable visceral sarcomata constitute a group of tumor cases of very great interest on account of their comparative variety, multiplicity of type and tendency to spread by metastasis. In adding five cases to the literature I have considered mainly the clinical aspects of each, with comments upon the relative frequency of similar growths, as far as the meager knowledge of the subject permits.

FIG. 1.—Case I.—Melanosarcoma of left eye, showing protruding tumor.

CASE I. *Melanosarcoma of Eye and Liver.*—The occurrence of melanotic sarcoma of the eye and liver is sufficiently rare to make the following case of exceptional value. The patient was a housewife, 34 years of age, whose heredity and previous personal history was unimportant. When first seen she presented a tumor of the left eyeball (Fig. 1) and a very large liver, in which numerous hard tumor masses were easily palpable. The eye symptoms covered a period of three years, commencing with darting pains and failure of vision in the left eye. Six months later the patient was operated upon for the result of an iritis and glaucoma. Subsequently hemorrhagic spots appeared in the sclera, and for the past year a tumor was observed protruding from the outer anterior surface of the eyeball and accompanied by much pain. Vision in the right eye remained normal. The patient's general health and nutrition were remarkably good until within a month of her admission to the Presbyterian Hospital, when she had frequent nausea with vomiting of mucus and sometimes blood, especially after eating. Examination of the abdomen revealed no pain or rigidity, but the liver, which extended almost to the pelvic brim, caused considerable bulging of the abdominal wall, over which area, as well as upon the face, there was much dark brown pigmentation in spots and plaques. Subsequently jaundice developed, there was hemorrhage from the gums, and the patient died from asthenia, with delirium, cyanosis and dyspnea. The autopsy, reported by Dr. Meakins, showed a melanosarcoma of the left eye, liver, perihepatic glands and pancreas. The spleen was normal, but the heart and kidneys presented fatty degeneration. Although there had been much hematemesis, the stomach exhibited merely a few submucous hemorrhages. The tumor of the left eye was black in color and projected at the outer side of the pupil 3 mm. above the conjunctiva. The eyeball was filled with a semi-fluid sanguineous mass. Section of the tumor revealed closely packed large, irregular spindle cells, in alveolar arrangement, but with very little stroma. Within and around the cells were masses of blood pigment.

The liver weighed 6,500 grams and measured 38 cm. in vertical diameter and 10 cm. in thickness. The transverse diameter was slightly less than the vertical. (In the accompanying photograph (Fig. 2) a normal liver is also shown for comparison). The liver stroma was nearly all replaced by tumor cells, identical in structure with those in the eye, but in parts the cells were deeply pigmented, in parts free from pigment, and in other areas there was pigment alone. Between the tumor lobules there was dense fibrous tissue. The glands at the liver hilum and along the pancreas showed similar tumor structure. The hepatic capillaries were smooth and glistening, mottled blood-red. The liver tissue appeared firm on section, but in some of the hemorrhagic areas an inch in diameter there was a semi-fluid mass. The pancreas presented small hemorrhagic nodules.

Striking features of this case were the long duration of the eye symptoms (three years), the preservation of nutrition in much greater degree than is usual with the carcinomas of the liver, and the absence of involvement of the stomach, despite the frequent hematemesis.

As the patient was not seen until within a fort-

*Read before the Practitioners' Society, February 4, 1910.

night of her death, it was difficult to determine whether the primary focus of disease was in the skin, eye or liver, but it is fair to assume that it was in the eye, for there was no history of an early pigmented growth in the skin, the eye symptoms were known to have lasted three years, and jaundice from compression did not appear until shortly before death. Moreover, primary melanotic sarcoma of the liver is almost unknown, and Hanot, in a review of the subject, could find only one authentic example. The coincident and relatively frequent involvement of the eye and liver is as obscure a morbid phenomenon as the origin of this rare form of tumor itself. Dr. N. R. Norton has lately informed me of a similar case of eye-liver association in sarcoma occurring at the Lincoln Hospital. John S. Thatcher[1] reported a case of melanosarcoma of the eye in which the liver was secondarily involved, and another of melanosarcoma of the liver alone.

Hirschberg (*Berl. klin. Woch.*, 1905, Nos. 4 and 5) reported two cases of melanosarcoma of the eye in which metastases were first observed in the liver fully 9 years later.

Fig. 2.—Case I.—Sarcomatous liver, weighing 6,500 grams. On the right a normal sized liver is shown for comparison.

Case II. *Lymphosarcoma of Mediastinum.*—The following fulminating case of lymphosarcoma illustrates the rapidity with which the disease may become fatal. The patient was a remarkably robust lad of 19 years, employed as a truck driver, who died within a month of the outset of symptoms and remained at work until a fortnight before death. He first noticed a diffuse uniform swelling of the face and neck, and fullness in the head with dry cough and slight dysphagia. There were no other subjective symptoms of any kind until within an hour of sudden death. On admission to the Presbyterian Hospital the patient's neck was symmetrically swollen, evidently as a result of venous congestion. The superficial veins of the neck, upper sternal region, shoulders and upper arms were greatly swollen and tortuous on both sides. In the left axilla and groin were a few moderately enlarged lymphatic glands. Across the lower thorax anteriorly were a half dozen red elevated plaques, about an inch in diameter, resembling urticaria, and in fact the eruption was mistaken for urticaria by a dermatologist who first saw the lad. I noticed, however, that although the redness disappeared on pressure, the swellings seemed firmer than the usual urticaria wheels, and in connection with the swollen lymph glands and mediastinal pressure, I regarded the case as one of probable lymphosarcoma, and directed the house physician, Dr. C. T. Roome, to excise one of the cutaneous tumors for microscopic examination.

Meanwhile the *x*-ray (Fig. 4) showed a heavy shadow in the upper mediastinum, through which masses resembling enlarged glands could be differentiated. There were no pulmonary symptoms other than an area of dullness corresponding with the shadow, and a tracheal compression type of breathing. The cough was brassy, like the laryngeal cough of aneurysm.

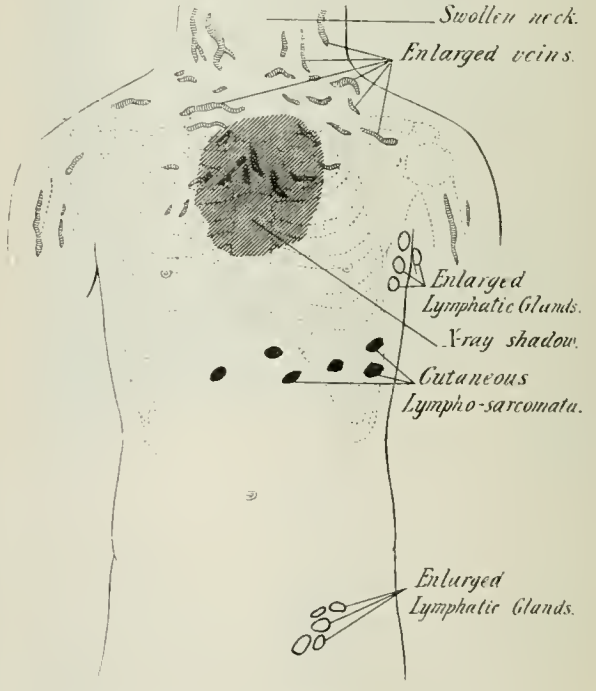

Fig. 3.—Case II.—Lymphosarcoma of mediastinum.

There was no fever, and blood count was practically normal, as follows: Hemoglobin, 95 per cent.; erythrocytes, 5,268,000; leucocytes, 11,600; polynuclear cells, 66 per cent.; lymphocytes, 33 per cent.; mast cells, 1 per cent. It was easy to exclude a diagnosis of aneurysm, abscess, tuberculosis,

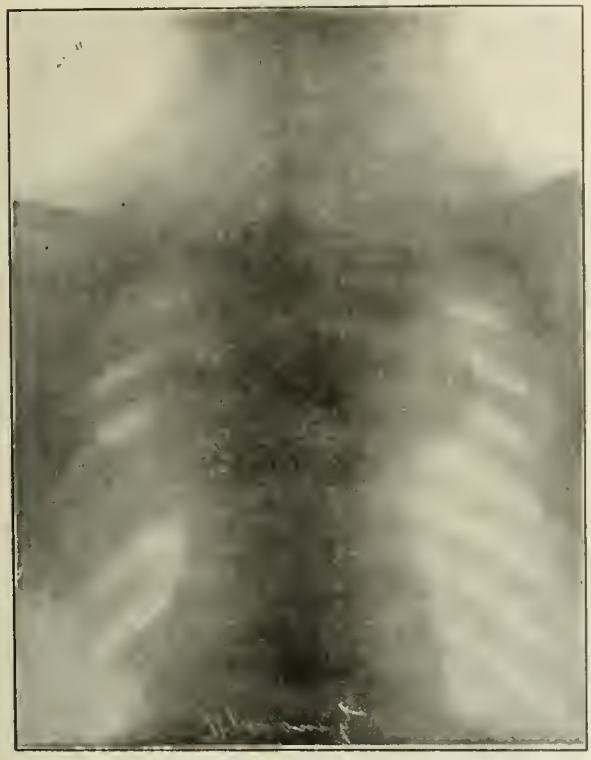

Fig. 1.—Case II.—Radiograph, showing thickening of neck, and extensive shadow in upper anterior mediastinum.

syphilis, and other types of mediastinal growth than the one suspected.

The pathological examination by Dr. Opie and Dr. Cecil of the excised tumor was as follows: "The tumor measured 10 x 6 x 3 mm., was attached to the skin, and had a leathery consistence. The corium was greatly increased in thickness and infiltrated with cells of lymphoid type, occurring both in masses and scattered form. There were karyokinetic figures and irregular nuclei; the subcutaneous tissue was infiltrated with masses and strands of lymph cells, the largest being grouped about the sweat glands. In these areas were eosinophiles. Diagnosis: lymphosarcoma."

On showing the section of the skin tumor to Dr. Ewing, he expressed doubt as to the possibility of classifying it accurately, the specimen presenting some suggestion of an epithelioma or alveolar sarcoma.

The patient felt so well that he was permitted to sit in a chair, when he was suddenly seized with intense gasping dyspnea, cyanosis, and an imperceptible pulse. Thinking the dyspnea was in part due to laryngeal paralysis, Dr. Roome intubated the patient and gave vigorous heart stimulation, but the patient died from loss of breath within an hour. Unfortunately for a complete clinical picture, no autopsy could be obtained, so it was impossible to determine the number and size of the mediastinal glands involved, except as they may partially be determined by the radiograph. The manner of death resembled that from enlarged thymus in childhood, and the thymus has been found involved in similar cases. The case is unique from the rapidly fatal course and the restricted development of secondary foci outside of the mediastinum.

The literature of mediastinal sarcomata is necessarily meager. In Hare's classical monograph on mediastinal growths[2] he excluded cases of sarcoma reported prior to 1870, owing to the imperfect technique prevailing before that date, but collected 98 cases reported in the succeeding nineteen years.

Among a total of 520 cases of mediastinal growths, nine of the sarcomata occurred in the second decade of life. Eight years later Irving S. Haynes[3] collected 18 more cases for an article in the Loomis-Thompson System of Practical Medicine.

Almost all the lymphosarcomata of the mediastinum are primary. They are of very rapid development, and usually involve the anterior mediastinum, originating in the thymus or tracheo-bronchial lymph nodes. Haynes suggests that the foreign material absorbed from the lungs or bronchi after inhalation and conveyed to the lymph nodes may prove an exciting cause by irritation. Sarcoma is the most frequent variety of histogenetic tumor occurring in the mediastinum, outnumbering the carcinomata three or four to one. The latter tumors, moreover, usually involve the posterior mediastinum, where there are more varieties of tissue from which they may develop, and they grow more slowly than the sarcomata, giving time for constitutional symptoms to arise. The case above reported corresponds in the site, rapidity of growth and absence of constitutional symptoms with these observations. Excepting the obvious swelling of the neck, the patient both looked and felt almost perfectly well until within the hour of his death.

Case III. *Melanosarcoma of Skin, Lungs, Heart, and other Organs.*—In contrast with the few secondary growths in the previous case, is that of a woman still under observation, who with sarcomata of the lung presents 185 tumors of the skin and superficial lymph nodes. Her history, in brief, is as follows: The patient is an Austrian, 40 years of age, formerly employed in a clothing manufactory. She was in good health until within nine or ten months of her admission to the Presbyterian Hospital. For many years she had had a dozen small, black pigmented moles distributed over the dorsal surface of both feet and the lower part of the abdomen. One of these, on the left foot, became bruised and irritated by scratching, so she had it removed. Shortly afterward she noticed a bunch of about a dozen nodular tumors extending downward in the left femoral region. These were also excised. A few months later numerous subcutaneous nodules began to appear all over the body, which have gone on multiplying and increasing in size, most of the 185 having appeared within a period of two months. They vary in size from a diameter of half an inch to two inches. They are most prominent over the lower thorax, both groins, middle of the back and both arms, but there are few areas of the surface larger than half a dozen inches in diameter where some may not be found. The larger nodules cause considerable elevation of the surface of the skin, but the skin appears movable over them. A few are somewhat bluish in appearance, but none are deeply pigmented. From time to time there is local pain over groups of nodules, but it is neither constant nor very severe. The nodules are painful when first appearing, but the larger growths are neither painful nor tender.

During the past few months the patient has lost

about thirty pounds in weight, and has complained of progressive weakness, fever, sweating, occasional vomiting, cough with bronchial expectoration (sometimes blood tinged) and occasional pain in the left chest, with a sensation of fullness there. She has also had chills at intervals. The examination of the urine, sputum and blood cultures are all negative. For a month after admission to the hospital the patient exhibited an abruptly septic type of fever, with daily fluctuations of about 4° Fahrenheit and a maximum rise to 105° Fahrenheit. (Fig. 5.)

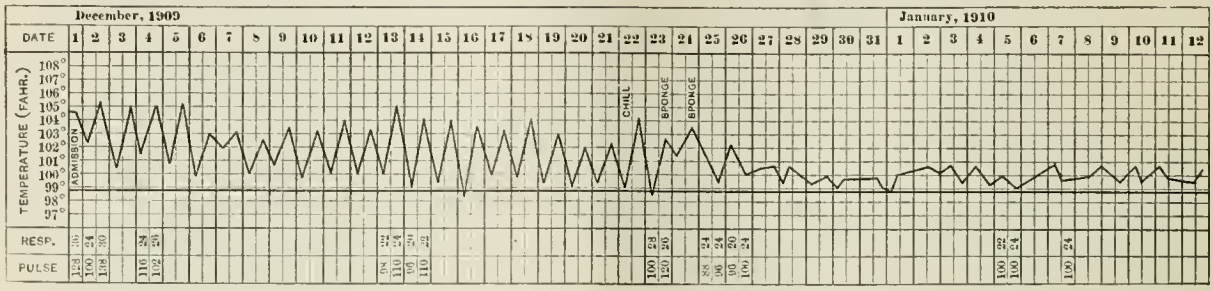

Fig. 5.—Case III.—Septic type of fever with universal sarcoma.

Explanation of this temperature was sought in the possible breaking down of one of the sarcomatous nodules, but none could be found, and the only demonstrable visceral involvement is in the left lung, which appears solid from the base to above the angle of the scapula. A radiograph (Fig. 6) shows this portion of the lung to be absolutely air free, aspiration gives a negative result, and the physical signs are those of dense consolidation over this same area in

Fig. 6.—Case III.—Radiograph, showing combined atelectasis and consolidation with sarcoma nodules of entire left lung.

which the patient has complained of pain and oppression. All the other viscera appear normal. The only adequate explanation of the prolonged high septic temperature would appear to lie in some disturbance of metabolism connected with the very rapid dissemination of so many new growths, but it was not accompanied by marked emaciation. In other reported cases of this type no mention is made of such a phenomenon, but it is well known that a similar irregular fever may occur during the course of Hodgkin's disease.

Blood examination is as follows: Hemoglobin, 67 per cent.; red cells, 4,840,000; leucocytes, 25,800; polynuclear cells, 82 per cent; transitional, 2; large mononuclear, 5; lymphocytes, 9; basophiles, 0.5; eosinophiles, 1; many plates. The last day of December, 1909, the patient attempted to get out of bed unaided and fractured the neck of the right femur. As the violence was trivial, the accident suggested abnormal brittleness of the bone. A partial fracture was demonstrated by the x-ray. (Autopsy showed the fracture to have been due to a metastasis in the bone.)

Previous to entering the hospital the patient had some sort of serum treatment, the nature of which could not be determined, but the result was negative. I asked Dr. William B. Coley to see the patient, and he was of the opinion that the case was of melanotic type, and not amenable to treatment by his serum. I had a subcutaneous nodule removed by Dr. Roome, and Dr. Cecil, of the pathological department of the hospital, reported that it was a neoplasm composed of round cells closely packed and supported by a scanty stroma. Blood vessels were found in intimate contact with the tumor cells.

The face and the feet are the sites from which melanomata of the skin most often arise. J. A. Fordyce[4] reports two cases originating from the foot, although he believes that the pigmented congenital mole is not a necessary antecedent of melanomata, for some of the latter appear without such association, and pigmented moles are exceedingly common in comparison with the rarity of melanoma. The case above reported illustrates again the well-known fact that metastases of melanomata are more numerous than those of any other type of cutaneous malignant tumor, although they are not invariably present in the skin in cases of visceral melanotic sarcoma. Thus none were observed in the eye-liver case above reported (Case I), although the disease had lasted two or three years. The reason for the rapid spread of the metastases sometimes seen in melanoma appears to be dissemination through both blood and lymphatic channels. The original idea that the melanin is derived from blood pigment is controverted by the fact that iron is absent, whereas sulphur is present in the dark amorphous granules, and another explanation which has been offered is that some form of nuclein becomes altered into pigment. Not all the cutaneous tumors contain pigment, whereas some are filled with it. In the case above cited the general appearance of those tumors which are nearest the surface varies from white to a distinctly bluish color, and in the specimen excised for exam-

ination no pigment was observed. This variation accords with the usual finding in similar cases which have been reported.

The disastrous result which so closely followed upon the removal of a pigmented mole in this case emphasize again the well-known possible danger of this procedure, and is a strong argument in favor of treatment by radium, according to Dr. Abbe's method.*

Case IV. *Sarcoma of Stomach, Heart, and Kidneys.*—This was the case of an Irish woman 47 years of age, who was in good health to within two months of her death, when she suddenly complained of abdominal, especially epigastric, pain, frequent nausea and vomiting, and weakness. Despite these symptoms she was able to perform house-work until within ten days of her death, although she lost about 25 lbs. in weight. There was no hematemesis or jaundice. The patient lived only four days after admission to the Presbyterian Hospital, during which time she had frequent vomiting, constipation, slight dyspnea and edema of the feet. The vomitus contained much mucus, with bile, pus cells, and red blood corpuscles. No hydrochloric acid was found, either free or combined. The urine was of low specific gravity—1009—and contained red blood corpuscles, fat cells, and a trace of albumen, but no casts. There was decided secondary anemia, the hemoglobin measuring 64 per cent. The leucocyte count was 9000, with 68 per cent. polynuclear cells and 26.5 per cent. lymphocytes. Examination of the large, flabby abdominal wall showed no rigidity or tenderness, but both kidneys were very large and palpable, the right one being markedly prolapsed. Palpation over the epigastrium gave the impression of a deep-seated mass, and the diagnosis of gastric carcinoma seemed justified. The patient died from exhaustion, and the suspected carcinoma turned out to be a sarcoma of the stomach associated with extensive secondary growth in the heart, kidneys, pancreas, ileum, colon, and mesenteric glands. The following is abstracted from the report of the autopsy by Dr. Cecil. The tumor mass in the stomach was hard, white, homogeneous and glistening and composed of small closely packed lymphocytes in a delicate fibrous stroma. It largely replaced the mucosa, and, in part, had ulcerated through it. The few remaining glands of the mucosa were atrophic. There were a few minor tumor nodules. In the ileum and colon were small flat tumor masses, oval, which in some cases appeared to occupy the Peyer's patches as well as to replace the mucosa. There were also necrotic areas. Microscopically the intestinal tumors comprised the same closely packed lymphoid structure as the stomach tumor. The heart weighed 385 grams, the valves and pericardium were normal, but in both ventricular walls were seen many smooth, pinkish, oval tumor masses about 2 cm. in diameter, without very distinct margins. Microscopically the tumors comprised the same type of lymphoid cells seen elsewhere, which were found to pack the intermuscular spaces and separate the muscle fibrillæ. The latter appeared intact despite the density of the new growth, which fact, in a measure, explains the remarkable absence of cardiac symptoms while the growth was in process of development. In certain other reported cases of sarcoma of the myocardium, a similar absence of symptoms has been commented upon.

The kidneys were very large, the right weighing 390 gm. and the left 430 gm. The capsules were nonadherent, and the normal kidney tissue appeared entirely replaced by nodules and irregular glistening white conglomerations of lymphoid cells. Many tubules and glomeruli were destroyed, others showed epithelial desquamation and distention with hyaline substance. The liver, spleen, and suprarenals were normal.

The infrequency of occurrence of sarcoma of the stomach may be gathered from a study made in 1905 by Corner and Fairbanks[5] of London, who collected 175 cases from the literature of primary sarcomata of the alimentary canal, of which 58 involved the stomach and 65 the small intestine. About one-third of these growths were of round-cell structure. Subsequently Norman Dalton[6] reported a round-cell sarcoma involving primarily the stomach and abdominal lymph nodes in a boy 15 years of age.

Harlow Brooks[7] reported in 1905 four cases of primary sarcoma of the stomach, one of which was of round-cell type, one a fibrosarcoma and one an angiosarcoma. His conclusion that sarcoma, while it is less apt than carcinoma to involve the gastric mucosa, is also less liable to form metastases, does not appear valid in view of the findings of the other cases herein quoted.

Sarcoma of the Heart has been less often observed than carcinoma, when the total number of cases of each are compared, but although sarcomata in general are less common than carcinomata, the relative proportion of sarcomata in the heart is somewhat greater. All varieties have been found in the heart, and although all are rare, the melanotic, round cell and lymphosarcomata are most often encountered. Less often cases have been recorded of the spindle cell, fibro-, myxo-, and osteosarcoma types, together with various mixed and doubtful varieties. As a rule the growths are secondary, but about a score of primary tumors have been reported, although in many of the latter cases the autopsies have not appeared complete as to microscopic details of other organs.

Curt Boether,[8] in an inaugural dissertation for the doctorate in 1897, tabulates 31 published cases of sarcoma of the heart, mostly from German sources, including four of melanotic type. They involved collectively all parts of the heart, two affecting the tricuspid valve.

Boruch Blumensohn[9] of Russia, in an inaugural dissertation for the doctorate in 1907, refers to 10 published cases of primary sarcoma of the heart, and a somewhat longer list of secondary growths, to which he adds 12 cases from the Pathologico-anatomical Institute of Basel, four of which were melanosarcomata. In six cases the valves were involved.

Ludwig Hektoen[10] has figured a remarkable spindle-celled sarcoma of the right ventricle, secondary to a growth in the tibia, occurring in a lad of

*Since writing the above description the patient died. Autopsy by Dr. Cecil showed an extraordinarily wide distribution of hard white sarcoma nodules, varying in size from a pea to several inches in diameter, which were of non-pigmented round-cell type. The spleen and liver curiously escaped, but nodules were present in their capsules, as well as in the pleura, bronchi, heart, pericardium, diaphragm, kidneys, suprarenals, thyroid, stomach, intestine peritoneum, abdominal lymph nodes, pancreas, ovaries, and bone marrow. The appendix was a mass of nodules, yet there were no symptoms of appendicitis. The destruction of the suprarenals gave rise to no bronzing of the skin. The nodules in the heart involved the septum auriculorum, and projected into the right auricle.

12 years.[7] In the same article he reports a primary round-cell sarcoma of the epicardium, and another case of a melanosarcoma of the right ventricle secondary to a growth in the breast.

A. Jacobi reported a case of fibrosarcoma of the heart, and S. W. Gross, one of round-cell type.

Epstein[11] reported the case of a male, 22 years of age, who presented a sarcoma of the stomach with secondary nodules in the kidney and a degenerated sarcomatous mass lying between the right auricle and ventricle.

E. Bonardi[12] reported a case of sarcoma of the heart secondary to a melanosarcoma of the choroid.

B. Luzzato[13] was able to make a correct diagnosis of a sarcoma of the heart secondary to growths in the leg and lung, owing to the supervention of a mitral stenosis while the patient was under observation. The diagnosis, which has rarely, if ever, been made correctly, was confirmed by autopsy.

Charles Norris described a case of melanosarcoma of the heart in a boy of 16 years which accompanied similar growths in the skin, kidneys, and liver.

The late H. P. Loomis[14] reported a case of diffuse round-cell sarcomatous infiltration of the heart and kidneys, secondary to a sarcoma of the breast, which was not unlike the personal case I have above detailed. (Case IV.)

Peter Neu[15] reported a lymphosarcoma of the left ventricle, "as large as an apple," apparently secondary to the removal of a tonsillar growth, and complicated by cerebral embolism.

Alexander Lambert[16] has described the case of a man 39 years of age, in which a small round-cell sarcoma involved the lung, pleura, pericardium, and left ventricle, which was remarkable from the fact that the patient was able to work shovelling snow until within a month of his death from dyspnea. The rapidity of development of this growth is analogous to that in Case II, above described.

John S. Thacher's[17] case was one of small round-cell type involving the stomach, with a secondary growth in the left auricle.

E. Libman[18] described a lymphosarcoma of the small intestine, the only one among 60 recorded cases in which there were metastases in the heart muscle.

Karl Bodenheimer[19] (Inaugural Dissertation) reported a case of primary sarcoma of the heart from the Bern Klinik.

Byron Bramwell[20] pictures a large double sarcomatous growth of the heart, one mass lying upon the exterior of the right ventrical, beneath the pericardium, the other situated within it, below the tricuspid valve.

The sarcomatous nodules may be situated within the myocardium, as in case IV herein reported, or lie upon it as in Case III, or beneath the endocardium, but are less liable than carcinomata to involve the pericardium unless by extension from mediastinal growths. The pericardium may, however, become affected separately, and Kaak has reported (1904) a myxocystosarcoma occupying this site. The usual pericardial growth takes the form of a diffuse infiltration.

A striking feature of all the reported sarcomata of the heart is the infrequency of associated embolism and cardiac rupture.

To this list I add the two cases above reported (Cases III and IV).

Case V. *Small Round-Cell Sarcoma of Stomach.*—The following case of lymphosarcoma of the stomach was operated upon by the late Andrew J. McCosh at the Presbyterian Hospital, and has not previously been reported:

The patient was a housewife, 39 years of age, who for a year had complained of gastric symptoms, mainly pain and vomiting, accompanied by loss of weight. Melena was present, and free hydrochloric acid was absent from the stomach contents. A mass of considerable size could be palpated in the epigastrium. A gastrectomy was performed, when the mass, which was the size of an egg, was found to occupy the pyloric end of the stomach, extending into the greater curvature. No secondary nodules were discoverable.

The tumor mass removed from the stomach measured 6 x 4 cm. It was hard and glistening, and composed of small round cells, larger than lymphocytes, imbedded in a small amount of stroma. The mass destroyed the submucous coat, and remains of the muscular coat were distributed through it. There was much lymphoid tissue also in the muscular coat, and the neighboring mucous membrane presented many ecchymoses.

Virchow[21] in his classical work, "Die krankhaften Geschwülste," stated the general proposition that "almost all those organs which show a great predilection for malignant tumor formation have little tendency to beget metastases, and conversely," yet the visceral sarcomata present so much variation in metastasis that it would seem unwise, with our present knowledge, to apply any such general rule to them.

Most of the 43 sarcomata received into the Second Division service of Bellevue Hospital during the past five years were sent in for operation, and the tumors of this group showed the usual predilection for the jaw, pelvic bones, and thigh. There were also seven cases involving lymph nodes in the neck, but in none of these latter, although the growths were multiple, was there any tendency to visceral or cutaneous metastases. One visceral case involved the kidney and one the occipital lobe of the brain, without metastases. The occipital tumor was as large as an orange, and caused blindness, deafness, headache, vomiting, convulsions, and noisy delirium. There was one case of lymphosarcoma of the intestine in a patient 53 years of age, but there was no involvement of the other viscera or skin. In two cases the tumor was situated in the right orbit, without extension to the liver or other organs. There were two cases of melanosarcoma of the skin with multiple growths which were very numerous. They were also without metastases, apart from the skin, at the time at which they were under observation. One of these cases involved the trunk and lower extremities, the other the trunk and upper extremities. The latter case was that of a man 50 years of age, who had canterized a pigmented mole. Six months later a nodule appeared beside the umbilicus and was excised, when five months later the tumors became generalized throughout the skin. This series of cases emphasizes the comparative infrequency of visceral metastases, even when the local growths had attained to considerable size, whereas in the four cases of my personal series, the visceral extension was the most serious part of the disease. As they belong to different species of sarcomata it is interesting to observe the extent of the involvement. That there did not happen to be any visceral metastases in the Bellevue series is doubtless due to the fact that the patients in many

instances came in for early operation, before the disease had spread.

THE SURGICAL MANAGEMENT OF URETHRAL STRICTURE AND ITS COMPLICATIONS.*

By EUGENE FULLER, M.D.,

NEW YORK.

In attempting to treat briefly an extensive subject like the one under consideration, salient points only can be touched upon, the idea being to acquaint the profession generally with the author's views, some of which are at variance with past teachings. A word regarding the pathology of, or what really constitutes, stricture is necessary to an intelligent understanding of treatment. Stricture signifies a narrowing more or less complete of the urethral caliber sufficient to cause noticeable obstruction to urination. Obstructions to urination or retention from other causes will not be here considered. Aside from the formation of granulation tissue which not infrequently developes on the urethral mucous surface at the site of a lingering inflammatory process and causes obstruction by choking the urethral caliber, urethral stricture is made up of round cell infiltration, of chronic urinary extravasation, or of true cicatrix. A given stricture may be made up of any one, of two, or of all three of these pathological elements. Those who have given little thought to the subject seem generally to suppose that stricture is made up of the third only of these elements, namely cicatrix. This faulty idea has in the past determined operative treatment to a large degree and recent surgical advancement in this direction has been possible only by discarding this idea and fully realizing that round cell infiltration and chronic urinary extravasation are the other and perhaps the more important elements. This feature will be taken up again in connection with the operative procedures.

The occurrence of false passage due to the unskillful use of instruments—and it may be that the term unskillful is far too mild an expression—is unfortunately a common complication in connection with urethral stricture. Such a complication is not only serious for the patient in that it predisposes to chill, retention, and sepsis, but it also often makes a grave operation necessary in a case where the stricture existing without this complication could easily have been managed without resort to the knife. The position of stricture, or, in other words, its location, whether in connection with the anterior or penile portion of the urethra or with the posterior or deep portion, is of some importance, since it may be that an anterior stricture can more generally be treated without resort to major operation.

A stricture caused by traumatism or as commonly termed traumatic stricture, generally represents a severe lesion and one not amenable to non-operative treatment.

Treatment of stricture without resort to the knife, often termed non-operative treatment, is really synonomous with treatment through instrumental dilatation. From time to time forms of treatment have been advocated in connection with which the claim has been made that stricture can be cured by absorption or otherwise through the topical application of medicaments or of electricity in some form. What has been found, however, when such claims have been impartially investigated is that whatever benefit may have apparently been associated with these methods has been due to the dilating quality of the instruments employed in applying the devices rather than to any curative virtues attributable to them. The only possible exception to this statement is, perhaps, in cases where the urethral obstruction is caused solely by a tuft of granulations. In such an instance it might be that the topical application of a solution of nitrate of silver or of some astringent would so shrink the granulations that temporary benefit might follow even though the granulations were not broken down and destroyed by the instrument making the application. The application of electricity so strong that the heat generated serves to open a way through a stricture by burning the tissue may, of course, temporarily seem to have removed an obstruction until the resulting contraction serves to rid the patient of his delusion.

The great majority of strictures are amenable to treatment by gradual dilatation. Many cases can be so radically relieved by such treatment as to justify the use of the term curative in connection with it. Most such cases, however, have from time to time to resort to more or less dilatation to guard against a recontraction. Skill in the use of bougies, sounds, filiforms, and other urethral instruments is a most important and necessary asset for any surgeon hoping to win a place of distinction in genito-urinary work. It is to be deplored that this subject has not received sufficient attention. Surgeons who are heavy handed in the use of these instruments are unfortunate, since they cannot retain their patients. A man who has to submit to urethral instrumentation is quick to detect the skillful operator and thankful for the slight degree of pain such a surgeon inflicts. Besides being thankful and loyal to the skillful surgeon, he is apt to loudly decry the one whom he has judged unskillful. That the patient also is unfortunate who falls into unskillful hands is often made evident by the frequent finding of false passages and other unnecessary lesions in connection with the urethræ of those who have been generally treated. The skillful oper-

*Read at a Stated Meeting of the New York Academy of Medicine Held March 3, 1910.

ator will very many times thoroughly relieve through urethral instrumentation patients previously supposed to be in such a serious condition that resort to the knife was imperative.

As a prelude to the subject of operative treatment the clinical history of the following case will be recited, the reason being that this case which occurred sixteen years or so ago served to revolutionize the ideas held by the author at that time and has always been looked back upon as a surgical experience of great value.

The patient, a hod carrier, thirty-five years of age, was referred to me as a supposed case of malignant disease involving the perineum. Examination showed in the perineal region extending from the scrotum back to the rectum a bulging fungous bleeding and oozing mass the size of a half orange. Palpation showed the entire perineum hard, infiltrated and apparently attached on either side to the rami of the ischii. The infiltration involved the deep urethra and extended upward to the apex of the angle of the pubes. It was found that no urine at all escaped from the meatus, but that all of it trickled through the fungous mass which tumefaction was discovered to be riddled with sinuses. An attempt was made to pass an instrument of some description along the urethra and into the bladder, but this was found to be impossible, the urethral occlusion being apparently complete. The patient was put in the lithotomy position and the attempt made to lay open the deep urethra, but the tissues were found to be so hard and cartilaginous in consistency that this effort failed. A section of tissue was, however, removed for microscopical examination. I then decided to establish a suprapubic fistula, thinking that the patient's distressing condition might be relieved by wearing a suprapubic drainage tube which could be connected with a rubber urinal suspended from a waistband. The patient remained in the hospital about four weeks and was then discharged with the suprapubic tube and the rubber urinal satisfactorily collecting the urine. The patient seemed then very comfortable. He was directed to come back to the clinic in a week or so for observation. Comparatively little attention had been paid to the perineum after the operation. The patient did not come back to the clinic as directed after his discharge from the hospital, and the case was rather forgotten for the time, though the report had come from the laboratory that there was no malignancy in connection with the tissue removed.

About six months after the time of this operation a robust, husky workman called at my office and made himself known as the individual whom I have just described as having discharged from the hospital with the suprapubic fistula. He stated that he was perfectly well and that urination was free and normal in every respect. The suprapubic scar was there, showing where the tube had been. The perineum was perfectly normal in appearance and palpation showed the tissues to be soft, yielding, and natural. A full-sized sound slipped into the bladder easily, showing no trace of stricture or in fact of anything abnormal. The urine was clear and free from bacteria or pus. The patient stated that he went to work as a hod carrier a week after leaving the hospital and for over three months wore the rubber tube and the urinal attachment. By that time he tired of the attachment, and as he thought he felt all right he removed the suprapubic tube and the urinal. In a short time after this the suprapubic fistula closed and he then found that he could urinate as well as he ever could. As he happened to be going by the office he called, although he had hesitated before doing so, as he thought I might scold him for disobeying orders in removing the tube.

I had certainly gotten a complete cure in this case, although the operation had not been undertaken with that happy object in view. The question arose how had the cure been accomplished? It was easily answered for all that had been done as far as the stricture and the perineal lesion were concerned had been to divert the urine from that region. In this case the urethral obstruction and the perineal lesion and tumefaction were made up of chronic urinary extravasation and round cell infiltration. The diversion of the urine had caused the extravasation to gradually disappear and the round cells had then been absorbed by the reestablished circulation, which finally completed the cure by healing the sinuses and the lesions of the urethral mucous membrane.

Shortly after this Moullin of London reported an important series of observations bearing on this same point. His cases represented stricture of the anterior urethra. In each case the caliber, extent and quality of the stricture was recorded. Then a perineal cystotomy was performed and a perineal vesical drainage tube introduced, the object being simply to divert the urine from the anterior urethra. The tubes were kept in place for about two weeks, if my memory serves me, and the perineal openings then allowed to close. A month or so after operation the anterior urethræ of these individuals were again examined. In a very large number of the cases the penile stricture had entirely disappeared and in the remainder marked and varying degrees of improvement were discovered. My own case and the confirmatory evidence furnished by Moullin were sufficient to establish in my mind the importance of the diversion of urine from a diseased urethral area, and in my subsequent operative work this principle has often been employed with great benefit.

One is commonly asked in regard to a case of urethral stricture whether internal or external urethrotomy is to be performed. Internal urethrotomy has been, and probably is still, by a majority of surgeons held to be the operation of choice for non-dilatable strictures of the anterior urethra. It has been years since I have performed the operation and I hardly expect ever again to make use of it. Enlarging by incision the meatus and the fossa navicularis is, of course, not classed in this connection as internal urethrotomy. The chief argument against internal urethrotomy is the danger of incurvation of the penis being left as a result. Hemorrhage and urinary extravasation into the sheath of the penis are other disagreeable dangers. Then, again, the curative results as regards the stricture are uncertain. The old idea was that the operation should be repeated in case a first result was unsatisfactory. Years ago in hospital clinics and in private practice it was common to observe the bad results wherein such multiple operations had been performed. One can, of course, see the fallacy of cutting in this manner through a stricture made up only of chronic urinary extravasation or of round cell infiltration.

External urethrotomy or urethrotomy accomplished through perineal section or incision is the operation generally advisable in the treatment of

strictures not amenable to non-operative methods. If the stricture be in the anterior urethra the incision into the perineum need be little more than a puncture with the knife, which puncture can be secondarily dilated sufficiently to allow the introduction of a perineal vesical drainage tube. As such a tube will serve to divert the urine and thus avoid the danger of postoperative penile urinary extravasation, it is consequently safe to then cut the penile stricture. The old rule in cutting a penile or anterior stricture in the performance of internal urethrotomy was always to make a longitudinal incision along the roof of the canal as one through the floor was out of the question owing to the danger of urinary extravasation into the sheath of the penis. The incision through the stricture, the perineum being open, can now be, and should be, made along the urethral floor, thus avoiding the vascular tissues lying about the urethral roof and also ridding the patient of the risk of being left with a postoperative cicatrix, the frequent cause of urethral incurvation, a complication which may be sufficient to so cripple the power of erection as to make sexual intercourse impossible.

Where the deep urethra is the part involved it is best to make a free median longitudinal incision extending from the posterior base of the scrotum down to the rectal sphincter, thus splitting apart the entire perineum and opening the whole length of the bulbous and membranous urethra. The diseased urethral area is thus fully exposed and the chance given the surgeon to do in an exact manner whatever may be necessary in connection with the urethral lesion. The question now comes up, what may it be necessary to do? This opens an extensive field for consideration, and is, of course, dependent on the character of the lesion existing in a given instance. It may be that the perineal incision along the urethral floor made for the purpose of exposing the deep urethra in connection with the perineal section so thoroughly divides the stricture that no more cutting is necessary. The finding of such an uncomplicated condition is not, however, usual. When the deep urethra is exposed it should be then carefully examined. To do this the perineal tissues should be made as taut as possible, this being accomplished by flexing the thighs back against the abdomen. The ordinary lithotomy position with the thighs simply vertical is not sufficient. One or two silk threads can be passed through the cut margins of the urethra on each side so that through the employment of gentle lateral traction the urethral surface can be thoroughly exposed. The existing lesions should next be repaired. Aside from stricture search should be made for pouches, diverticula, and false passages. These, if found, should be cut out and the urethral roof made so smooth that a curved steel sound of small caliber used by way of a test can be demonstrated to pass without being obstructed. If the deep urethra so exposed is found to be markedly constricted by annular stricture, the cut through the floor may not be sufficient to establish a full caliber to the canal in the area involved. That being the case, a longitudinal incision through the roof also of the urethra in the constricted area is advisable, sufficient to restore the caliber. In severe instances of urethral stricture where much structural disorganization exists, as is not infrequent, especially in cases of traumatic stricture, simply cutting through the urethra, in the manner described, may not be sufficiently radical. These are the cases to which the operation of urethral resection is usually applied. Formerly my ideas in connection with urethral resection were more radical than at present, and I now find myself cutting away far less tissue and with much better results than formerly. In cases where severe deep urethral disorganization apparently exists, the case of the hod carrier previously related comes to mind, and in them it is better surgery to first do the suprapubic cystotomy, divert the urine from the urethra and then later, as a secondary operation, if such be necessary, open the perineum to repair what remains of the original lesion. In operating on the deep urethra in cases of the class usually demanding resection, my rule is before removing any tissue to first make the longitudinal cut through the urethral roof. This cut should extend along the entire area of the stricture and should be so deep as to fully divide the strictured tissue. Then with curved scissors cicatricial nodules should be cut away from both lateral strips of urethral tissue. Such cutting away, however, should not be extensive enough to remove all the outlying layers of these strips, but enough tissue should always be left to guard against a breaking away and a retraction of either strip. This operation is at most only a partial urethral resection, the one of complete resection having been by me abandoned except in cases where the urethra has by reason of some previous process, such as gangrene, disappeared in a particular area.

The surgical treatment of the strictured area after the cutting, such as described, has been accomplished, is next in order. The old and ordinary postoperative feature of passing a steel sound every few days so as to prevent the cut urethral surfaces from growing together and thus reforming the stricture has been by me wholly abandoned. I have always considered this practice most objectionable. It was the frequent cause of urinary chill and sepsis due to the breaking down of the agglutinated tissues. To guard against such resulting sepsis from becoming serious, the perineal incision was necessarily left open to close slowly by process of granulation. Perineums so left open not infrequently failed to close completely, a urinary fistula persisting. Such fistulæ would be especially apt to result in cases where the perineum had been freely opened so as to allow a thorough exposure of the strictured area, such as I have recommended. Accordingly, if sounds were to be used in the after treatment and the perineal wound left open the incision into that part should be narrow, too small, in fact, to allow a careful or complete operative treatment of the stricture. The trauma caused by sounds in these cases also tended to produce a dense cicatrix, besides inciting round cell infiltration and urinary extravasation into the raw areas after the urine began to pass by the urethra. To obviate the use of sounds and to allow a suturing of the perineal incision, I make use of the "urethral splint." An ordinary perineal vesical drainage tube is first passed along the lowest part of the perineal incision into the bladder. Next the urethral splint, a rubber tube the full caliber of the urethra, generally 30 to 32 Franch, is passed along the urethra and down to the perineal tube. The lower end of the splint is cut off at an angle so that it fits snugly to the perineal tube. The deep urethra is then sutured over the urethral splint and the perineal incision closed except for the tract along which the perineal tube passes out. The splint and vesical tube are usually kept in position ten days. Ten days after the removal of the splint it may be well to gently pass a moderate calibered

blunt-ended sound to see that no granulations have formed, but in no case should a conical sound of large caliber be used for the purpose of stretching the tissues at the seat of operation.

Hemorrhage severe and difficult of control may be encountered in connection with operation for deep stricture. Such hemorrhage may be primary, that is, in connection with operation; or secondary, not occurring perhaps for eight or ten days after operation. The old and extremely inefficient device known as the "shirted" cannula used to be employed to control such hemorrhage, or packing was pushed in about the perineal tube. Both these devices simply temporarily stopped the external flow of blood. The bleeding being diverted backward, the bladder would become filled with clot. This would result in retention of urine, and tenesmus would follow. Such tenesmus would increase the tendency to hemorrhage, and then the bleeding forward would begin again in spite of the packing there employed. Most such cases so managed terminated fatally. Such hemorrhages can be effectually controlled, and the life of the patient saved by promptly opening the bladder suprabically, removing the intravesical blood clot and then packing the perineal wound, both intravesically—retrograde, as it were—and externally through the perineum. In such a case the perineal drainage tube should be removed, so that the packing may be complete and a suprapubic vesical drainage tube inserted. This radical treatment immediately frees the patient of all tenesmus, so that there is no danger of a displacement of the packing until such time as it can with safety be removed. Hemorrhage which may take place during operation and which can only be checked in the manner described generally occurs in connection with the cutting through of strictured tissue or the removal of such tissue in cases where the lesion lies above the deep urethra and extensively involves the structures in the apex of the angle formed by the convergence of the rami of the pubes. In this narrow space it may be impossible to compress a bleeding vessel by the ordinary appliances. Secondary hemorrhage may be from any vessel along the tract of the wound.

Perineal section, without a guide, is classed as one of the most difficult operations of surgery, and when one watches an operator not especially skilled in this particular making a demonstration of this procedure, the classification given to the operation seems correct. The operation ought not, however, as a rule, to prove tedious or to strike the observer as especially difficult if only the operator bears in mind the directions here recommended. A urethral instrument, often a whalebone filiform, is first passed as far as it will go and then the perineum is laid open in the median line along its entire length, just as has been already described. The first attempt of the operator should be not to cut down on the end of the urethral instrument, but to open freely the normal urethra anterior to the stricture in the upper portion of the perineum. This will allow a minute inspection of the anterior face of the stricture. As the stricture is carefully exposed, it is often found that the end of the arrested filiform or instrument employed lies at the bottom of a false passage, and is consequently in an extra urethral position. In such a case a careful examination of the urethral surface with a probe in the region of the anterior margin of the stricture will generally reveal the urethral channel close by the entrance to the false passage. If the true entrance is not so found a gradual opening of the cicatrix in the median line associated with the frequent and careful prodding of the probe along the surface as it is exposed will soon reveal the channel except in cases where complete urethral disorganization exists.

Where complete urethral disorganization exists and no urethral tract can be followed through an exposure of the part by perineal incision, it is, of course, then possible to perform suprapubic cystotomy, and by resort to retrograde catherization to cut down on the projecting end of the retrograde instrument, thus locating the posterior face of the stricture. The next step can be to remove by resection the disorganized structure, make use of the urethral splint, and close the perineum around it as already described. Although the employment of retrograde catheterization can be and is of great value, I personally should now hardly expect to find a need for its use to help me out in a case wherein I had failed to enter the bladder through the aid of the perineal opening. I make this statement because I do not consider it wise to try by one operation to repair and cure extensive deep urethral disorganization. Extensive deep urethral disorganization is almost always associated with complications which make it inadvisable to try to repair the disorganization while these associated complications remain. The only exception to this rule is in connection with traumatic rupture of the urethra wherein the patient comes to operation very promptly after the accident, extravasation of urine not as yet having had time to take place. In acute disorganizations of the deep urethra which signifies a rupture of the part by some form of traumatism, acute extravasation of urine, gangrene, and abscess are the resulting associated complications. In lasting or chronic serious disorganizations, abscess formation and burroughings, fistulæ, chronic extravasation, and infiltration are the associated complications. In all such cases the primary operation advisable is a diversion of the urine through the establishment of suprapubic fistula, together with free surface incisions into the perineum in those of them wherein urinary extravasation, gangrene, or abscess coexist. The perineal incisions in these cases are simply for drainage. Then at the end of three weeks or so the deep urethral lesion, being free from complication, is in condition for a secondary or repair operation. In connection with that secondary operation it may be that retrograde catheterization will be found useful. If so, the instrument can be easily passed through the suprapubic fistula. In cases wherein perineal gangrene has existed, a considerable section of the urethra, together with much of the perineal structure, may have been destroyed. It is in these cases that a series of plastic operations may be required in order to reestablish the urethra and to close the perineal opening. In such cases I have found it advisable to first try to reform the urethral roof by resection and the application of the urethral splint, and then by a later plastic operation to close the urethral floor. In such a plastic operation flaps from the buttocks and scrotum have to be utilized. In these cases where deep and firm suturing is very necessary I have made much and satisfactory use of metal cleats to securely hold the sutures and to maintain the flaps in position. To serve the purpose of such cleats, 25-milliampere fuse sold in electrical supply shops has been found most serviceable. A special consideration of this interesting topic would, however, be beyond the range of the present paper.

252 Lexington Avenue.

FREUD'S VIEWS ON THE MECHANISM OF HYSTERIA.*

By JOSEPH SMITH, M.D.,

AND

MARY L. NEFF, M.D.,

LONG ISLAND STATE HOSPITAL,

BROOKLYN, NEW YORK.

The mechanism of hysteria is explained by Freud as follows: Any experience of a painful emotional character may be called a psychic trauma. If such experience is not reacted to adequately and appropriately it remains in the mind and gives rise to an "affect-memory"—the term implying the recurrence of the emotional element when the memory of the original experience is recalled. This "affect-memory" remains in the subconscious mind, acting somewhat as a foreign body does in a somatic way; and if sufficiently organized may usurp control of the bodily innervation, as well as of the psychic activities, thus producing various hysterical phenomena.

The causes of psychic trauma, as postulated, are (1) severe emotional experiences, or (2) experiences in themselves inadequate, acting on a predisposed subject. Every gradation between a predisposed and an acquired hysteria exists, the required trauma being inversely proportional to the predisposition. The so-called "idiopathic" cases of hysteria Freud believes to be merely those in which the trauma cannot be discovered, though really existing.

The psychic trauma may consist of a single experience, or of a group of experiences; or it may result from indifferent occurrences coinciding with a time of special nervous susceptibility, as a state of fear. To illustrate this the following cases, among many, are cited. A patient had a painful emotional experience during a meal. This acting as a trauma, produced nausea and vomiting, which persisted for months. A second patient while in a semi-conscious state had terrifying hallucinations. As a coincidence her right arm, which was hanging over the back of a chair, fell asleep. Subsequently she developed in this arm anesthesia and hysterical paralysis with contractures.

The connection between the psychic trauma and the resulting phenomena may be obscure. In examining patients it is often extremely difficult to elicit the history of the original experience which acted as a trauma. Often it has been entirely forgotten by the patient, and here the value of hypnosis is obvious. Moreover, these experiences are often unpleasant to relate, and even difficult to a marked degree, as the habit of inhibition in regard to them is frequently firmly established.

The affect-memory may produce a single acute attack of hysteria, or a series of more or less persistent symptoms of a hysterical nature; or, as more frequently happens, the result may be a combination of these two. The individual symptoms are Protean, covering the entire range of psychic, motor, secretory, and sensory phenomena. Even when the symptoms are purely somatic it may be postulated that a submerged affect exists.

Hysterical attacks may occur (1) spontaneously, as in times of fatigue, or under other conditions in which dissociation takes place readily; or (2) they may be provoked either (*a*) directly, when the affect-memory is recalled, or (*b*) indirectly, through some experience analogous to that which caused the trauma—the hysterogenetic zone responding to excitation in both instances.

Before considering the peculiar reaction to psychic traumata which forms the basis of the hysterical state, the normal manner of reacting should be called to mind. A certain degree of fading ordinarily occurs with the passing of time in regard to any memory. Even when the recollection is retained the affect disappears. We do not weep over the remembered woes of childhood, nor resent the slights of years long past. This fading, however, takes place normally only when the individual reacts adequately to the experience, and finds full expression for the affect in its appropriate reflexes. Speech alone may be an adequate reaction, as in the confessional; or full expression may require voluntary or involuntary reflexes, from weeping to an act of vengeance. The common saying, "cry it out," shows a general conception of this necessity for an adequate reaction, and the use of the word "mortification" for a silently borne injury suggests its traumatic nature.

A second method of righting a psychic trauma exists. The experience may become incorporated in the general complex of associations which constitutes the normal consciousness, arrange itself with other experiences and suffer correction; as when fear is gradually effaced as the fact of present security is realized. An experience involving chagrin or humiliation will be similarly corrected by the consideration of one's dignity or importance in a general way.

Many causes may prevent adequate reaction from taking place. These causes fall naturally into two groups.

The first group includes (*a*) experiences to which no reaction is possible, as the death of a loved one; and (*b*) those which the individual voluntarily excludes from the field of consciousness, as often occurs in regard to sexual matters, the elaborative processes of association ("apperception") being thus inhibited. Here the nature of the trauma excludes the reaction.

In the second group the normal reaction is prevented by the nature of the attending circumstances. We may have (*a*) experiences accompanying fear, or other severe affects; or (*b*) occurring under abnormal conditions, especially the dissociated states of consciousness, such as revery, autohypnosis, etc. In the latter case no associative binding takes place between the normal and the abnormal states of consciousness.

An affect-memory may belong to both of these groups at the same time. A trauma occurring in a state of dissociation which prevents its being righted by its proper reaction does not tend to right itself by subsequent associative elaboration, as would occur under normal conditions.

The phenomena of dissociation are analogous to those of dreams. As in a dream we have experiences and emotions quite detached from our waking consciousness, so in the condition to which Freud applies the term "hypnoidal" the experiences are detached from the normal consciousness. Dreams, however, do not influence the waking state, while the products of the hypnoidal condition obtrude themselves into waking life as hysterical phenomena, sometimes affecting the bodily innervation without affecting the consciousness, and sometimes

*Read before the Brooklyn Society for Neurology, Feb. 25, 1909.

appearing in the psychic life. In either case, they lie outside the stored-up memories of normal consciousness.

Even in normal persons a severe psychic trauma or a forced suppression of an affect brings about a splitting of groups of ideas. We often say a person is "distrait" or "absent-minded" under such conditions. In time, however, the associative processes deal with these experiences so as to assimilate them, and the memory of them fades away. In hysterical subjects, however, the split-off group remains split-off, and long retains its original vividness.

A series of hypnoidal memories may associate with each other and obtain a high degree of psychic organization, thus forming what may be called a "second self." Both the degree of organization and of exclusion from the normal field of consciousness vary greatly, ranging from the merely rudimentary second self which exhibits hysterical symptoms, to the highly organized "second personality," which may usurp control in a severe attack of hysteria.

The pathogenic complex frequently has somatic sequelæ, such as motor phenomena, which the normal consciousness may perceive during the attack without any knowledge of the psychic accompaniments. Each hysterical attack acts to some extent as an additional trauma, thus reinforcing the tendency to subsequent attacks.

The two psychic conditions—*i. e.* the normal consciousness and the hypnoidal consciousness—tend to establish a system of alternating activity which admits each assuming control in turn without really influencing the other.

We come now to the notably valuable contribution which Freud has made to the therapeutics of hysteria. He applies the name "psychoanalytic" to the following method of treatment, which consists of two distinct steps. First, the original exciting cause of the hysterical symptoms must be fully recalled to mind. This may be accomplished by careful questioning on the part of the physician, or by suggestion with or without full hypnosis. Second, the accompanying affect must be fully expressed or reacted to in speech or in action. To this second essential step in the therapy of hysteria Freud has given the name "catharsis." The first step without the second is unavailing. "The entire psychic process which has taken place must be repeated as vividly as possible—brought back to its 'nascent state,' so to speak—and then expressed."

In some cases this treatment will effect a permanent cure immediately. In others a gradual disappearance of the psychogenic complex will be brought about by the normal processes of association, after the affect-memory has been restored to the field of consciousness. As these buried complexes are often long forgotten, though not extinct, hypnosis is frequently most useful in bringing them to light. Often the same result may be accomplished in a semi-hypnotic condition where the patient is merely in a suggestible mood.

The hysterical diathesis, of course, cannot be removed by this or by any method; but, as "the hysterical suffers mostly from reminiscences," in this way he can be freed from the cumulative effect of past traumas. This method (of catharsis) is ineffective during the productive stage of an acute attack, since as each hysterical phenomena is removed it is quickly superseded by another.

The question might arise whether the expectation of cure by the patient acts as an unintended suggestion, thus forming a potent factor in causing the cure. Freud thinks this is not the case, and refers to the fact that the first cure was brought about unwittingly (in 1881, before the era of suggestion) by a successful attempt to bring to light and explain the submerged affect-memory in a hysterical patient. The recovery which followed was an entire surprise to the physician, who was unaware of the therapeutic value of the procedure.

THE ATHLETIC LIFE IN ITS RELATION TO DEGENERATIVE CHANGES IN THE CARDIOVASCULAR SYSTEM.*

By ROBERT E. COUGHLIN, M.D.,
BROOKLYN, NEW YORK.

The present time appears to be an unusual one for great interest and activity regarding athletics. No doubt the popularizing of school ahletics has contributed in a measure to this interest. A short time ago a gentleman said to me: "Doctor, I have two boys attending high school who wish to take up athletics. Would you advise against such contests?"

This is a rather difficult question to answer offhand unless one knows the boys thoroughly both in regard to their constitutions and temperament. Hereditary influences as well as idiosyncrasy also play a part. Given a boy with a certain constitution and temperament with no tendency to any organic weakness, we could decide very promptly, but a review of all the available literature may help us to a certain extent. As a rule it is impracticable to generalize respecting a subject of this character, the personal equation at all times being a very important factor.

To make it a little easy to discourse on the theme, we shall consider the subject matter from several standpoints and subdividing the same according to the age of the individuals. For obvious reasons the male sex alone will be considered, as up to the present there is really little indication of girls and women becoming athletic in the sense that it is generally considered in boys and men. We note, however, the sudden death recently of a young girl who excelled as a basket-ball player, the autopsy revealing a large heart, which the coroner's physician believed was due to her athletic life.

The four ages to consider will be early life, including infancy, boyhood, youth, and adolescence up to the twenty-first year; manhood, from the twenty-first year up to the fortieth year; middle age, from the fortieth to the fifty-fifth year; beyond middle life up to old age.

It is easy to understand that the same advice could not be given in a general way to the different persons constituting these divisions, and that indeed it would be difficult to advise the same treatment to the different persons constituting any one division, but in a general way, for convenience sake, this may be done; and so we shall consider each class or division from several standpoints: (1) from the standpoint of the same being a benefit to the individual; (2) from the same being injurious to the individual, either temporarily or permanently.

Beginning with infancy, we may observe the inclination of the child toward activity. When healthy and well he is very active during his waking moments, and he has the power which nature gives him to exercise both his voluntary and involuntary muscles. Nothing can compare quite with the grip of the infant. He likes to grip, and he grips at all times in an extraordinary manner. When he starts

*Read before the Brooklyn Pathological Society, December 9, 1909.

to walk he does so because the time has arrived for him to use his lower extremities as well as his arms and hands. Once the art of walking is learned, he is on the way to great activity. He covers many a mile in a day, and would rather run than walk at any time. At all times he seems to have surplus energy.

Soon he reaches "the savage age when a boy abhors all regular occupation." The play problem is fairly open. It is well said, "the boy without a playground will become the father without a job."

The seventeenth is the healthiest of all years for boys, yet the eighteenth is sickly. The year of lowest death rate or greatest power to resist disease is the thirteenth. The mortality is less for girls than for boys in the period preceding puberty.

In a discussion regarding athletics in boys' schools a middle ground seems to be occupied by the Medical Officers-of-Schools Association. Says *The Hospital* (April 3, 1909) in an editorial: "These medical officers adopt the extreme position of neither side; that is, they advocate neither grandmother coddling nor the Spartan survival-of-the-fittest attitude of many athletic persons. They point out that neither age nor distance is in any way an exact criterion of the strain inflicted on any given boy by any given race. The quarter-mile is a far more exhausting race for most boys than are the long-distance races; and to this we would add the half-mile, in which schoolboys have done at various times very notable performances, but, now and then, with considerable detriment to themselves. The association lays it down that the plan of running all the boys, old and young, over the same course or distance is not to be recommended; but we are not sure that in this particular we quite agree. For if a separation is made it must be on some rough line, such as age; and that means that a compact, well-developed youth capable of any exertion may be sent into a junior division to set the smaller boys a hot pace over a short run, while an overgrown and much less precocious boy a month older may be put to compete with the most athletic of his fellows over a longer distance. When all the boys run together, the best runners may finish a five-mile cross-country run half an hour before the worst, but at the same time this gives those who, by reason of youth or retarded development cannot excel at this exercise, a chance to complete the run and benefit by it without undue strain. Provided there is a thorough medical examination of every boy on entering school, provided that the effects of various games on the younger boys are carefully supervised, provided that certain common-sense rules, which boys themselves do not appreciate, are enforced upon them, then the risk of ordinary school exercises, including cross-country runs and flat races not exceeding one mile, is so reduced as to be quite negligible. If the masters and school medical officers do their duty in observing the limits laid down by the association, parents may safely leave their boys to follow their own inclinations and their school traditions in these matters without fear of the consequences."

Dr. Tyrrell Brooks of Oxford has said it was his experience that the most vigorous undergraduates came from the schools whose athletics were of the most strenuous type. Of the organs likely to be damaged from athletics in excess the heart was the chief. Valvular damage, due to exertion, was very rare, but it was to be remembered that slight dilatation of the heart was difficult to estimate. It was almost certain that the natural resilience of the heart was so great in boyhood that mere muscular exercise could hardly seriously damage the heart. Special care in permitting active exercise after convalescence from acute illness was a very important precaution. On the whole, the trend of opinion among British medical men was distinctly favorable to athletics under proper condition and supervision.

H. H. Riddle of Cambridge University, England, believes that the athlete, if he has been sensibly trained and has not noticeably overstrained his powers in his youth, has the best chance of a healthy and active old age. In reference to the difficulty experienced by British authorities in obtaining physically strong recruits for the army a writer has the following to say: "It seems to be at least generally recognized that the mind is not likely to be healthy unless the body is in sound condition."

An American writer states that New York City has more than 200,000 young aspirants for record-breaking honors in its Public School Athletic League. In the country at large are about 10,000,000 amateur athletes, a large proportion of whom are still in the growing age.

Dr. Brooks of Oxford says that in coming to any conclusion as to the precise value of athletics in causing morbidity of the heart it is necessary to know the history of the patient under examination, as excessive smoking, abuse of alcohol, gluttony, insufficient rest—any or all might enter into a young man's life and produce exactly the same symptoms as were attributed to athletics.

Dr. Moritz had a good opportunity to study the hearts of several wrestlers after severe exertion which their occupation demands. In no case was there any dilatation of the heart, and like results were noted in several bicycle riders (*Münchener med. Woch.*, June 23, 1908). Indeed, Moritz claimed to have noted even a diminution in the heart following moderate or severe exertion. The possibility of an acute dilatation is not denied by the author, but such a phenomenon, according to him, is a sign that the heart is not free from some pathological defects.

In summing up the work of Dr. Benedict and Dr. Carpenter which was done in Wesleyan University, a medical editor has the following to say: "The human body is a machine of such a degree of efficiency that one-fifth of the energy expended by it can be utilized as work, and that this efficiency is constant in men of all types. The longest and the most thorough training does not change this ratio. The professional athlete, if he is able to do more work than the novice, does it not because his muscles are of such a quality that he can get more work out of them from the same amount of energy, but because he is able to put more energy in the shape of tissue change into the action. It would seem then that training, besides preparing the heart to stand greater strain, acts to increase the subject's power of using up his tissues and by giving him more muscle tissue to use rather than by teaching him to conserve his energies. To adopt a metaphor from the mechanical world, the professional has a more powerful engine because he is able to use more fuel, not because he wastes less steam.

Dr. Roeder of Berlin has presented an interesting report at the Union of the Berlin School of Physicians on the hygienic results of walking trips. He examined school children before and after a walking tour to see whether the favorable results of such a trip were only subjective, or whether objective benefit occurred. Fifty-six children were sent on walking trips in three groups, each under the leadership

of a teacher. The children walked on an average ten to twenty miles a day. For breakfast they were given coffee, milk and white bread, during the day bread and butter, and in the evening a warm dinner. As the result on body weight one series of well-nourished, strong children did not change weight during the six days' tour. A small number either lost weight or gained from one to three pounds. It was of interest, however, that during the following three months fifty of the fifty-six children gained weight from three to twenty-two pounds. From this it would appear that the violent muscular exercise stimulated the organism to increased metabolism and more rapid growth. Especially of interest is the comparison of nine girls who took the tour with twelve from the same school who had not been on the trip but had taken vacations at the same time. The girls who had walked gained 6.7 pounds during the next three months; those who had not walked only 4.8 pounds.

We shall now take up the unfavorable reports and statements relative to the subject, as up to the present all the testimony appears to be more or less favorable. Mr. R. H. A. Whitelocke of Oxford has explained the phenomenon of "second wind" by supposing a kind of physiological emphysema to be produced in the lungs, due to the violent exercise. The first effect of violent and sustained efforts was dilatation of the heart, the right ventricle being first affected. Those who had been subjected to or who had suffered from heart strain in youth seemed to show a distinct tendency to recurrences in later life when attempting such exercises as mountain climbing. One writer states that on numerous occasions the competitors in feats of endurance have been subjected to careful medical examination before and after the event, nearly always with the result that a warning has been uttered against indiscriminate efforts to obtain the fame that is to be gained in this way. That while such feats of endurance may not necessarily be followed by directly injurious consequences, they involve the risk of producing districts of lessened resistance which at a later time may invite serious organic disease, and that these hazards are especially great in youthful individuals.

One medical officer of one of the National Guard has said that he did not believe that professional athletes should be recruited, as they made poor soldiers.

There appears to be any amount of evidence against Marathon races. During the past year a number of deaths have occurred. Fallen runners along a Marathon course, many in a state of exhaustion verging on collapse, while others are reported delirious, is testimony enough that such races menace athletes. In commenting on these races one writer closes the subject as follows: "Charles Kingsley's praises of 'muscular Christianity,' of the cold plunge, and the hard fought field cost England, it is said, the lives of thousands of young men whose courage and will power were stronger than their bodies—often precisely the young men who were of most value to their country. Parents, teachers, trainers in athletic clubs and others in authority are in a position now to check a similar sacrifice."

In a humorous vein one writer asks the following: "Melvin W. Sheppard's successes at the Olympian games are frankly insulting to the New York police surgeons who rejected him as physically unfit to enter the department. What business has a man whose heart is officially condemned by the second largest city in the world to win victories in international athletics?" Another asks the following question: "What is invalidism or disability to one who has made a record, and how trivial seems the hypertrophied heart to the winner of the Olympic games?"

Dr. Warren Chapin is quoted as being very much opposed to school athletic contests. He states that school athletic competitions push the young well-nigh beyond the limit of their endurance and unfit them for their present and for their work in after life. Dr. Charles E. Quimby has said that the effect of this over-indulgence in athletics nowadays is a general breakdown. Neither Dr. Chapin nor Dr. Quimby will allow their sons to take part in competitive athletics that call for extreme exertion.

The death of Griswold early in January of this year was a blow to rowing races. It was occasioned, it is said, by typhoid fever, which was preceded by shattered health dating back to the Yale-Harvard race of last year, when Griswold, Yale's stroke, collapsed in the boat.

The conclusion that college athletics is not injurious, deduced by Dr. William G. Anderson, director of the Yale gymnasium, from mortality statistics of the graduates of the university, is declared by *American Medicine* (Sept. 1908) to be most dangerous. The picked men of the teams, the writer thinks, should show a far lower mortality than the average, and should be extra good risks. Boys need not be stimulated to develop a fatal degree of musculature; if anything, they need restraint. Numerous instances may be mentioned of record holders having been compelled to give up athletic work because of organic disease. Two examples of late are Whitney and Ewry.

From the twenty-first year to the fortieth little may be said of the evil effects of athletics as most young men have by this time passed out of athletic life and gone into their chosen vocations. The eagerness to make a living and the desire to succeed in life compels them to be up and doing. As a rule degenerative changes are not so apparent, and though the man may be working under high pressure, no notice is taken of such changes till middle life is reached. This is the time, however, when habits of life are formed. The enlarged heart may call upon the ex-athlete for some stimulation, and instead of exercising he takes to drink or maybe opens up a saloon. Once athletically inclined, always athletically bent, would be a good rule. When Dixon, the lightweight pugilist, died last year the writer communicated with the physician in attendance for the purpose of finding out the real cause of death. The reply he received was to the effect that his patient died of myocarditis preceded by alcoholism. The fate of his successor to the title was pretty much the same except that he was attacked with a mental disorder and now resides in a sanatorium.

At a meeting of The Medical Association of the Greater City of New York in which the athlete's heart was brought up for discussion by the writer of this paper (Medical Record, February 8, 1908) Dr. William Henry Porter said that he was glad the question of the so-called athletic heart had come up for discussion, as it was very important, and, like all other affections of the heart, required a clear conception of the laws governing the nutrition of the heart muscle to be fully understood. The one thing to be remembered was that the nutrition of the heart and of all the tissues of the body depended upon a uniform expansion and contraction of the

ultimate arterioles, so that the blood could be passed slowly or rapidly through the arterial capillaries, at which point all nutritive interchange occurred and was regulated, according to the demands of the tissues. By destroying this peculiar physiological control, the varying forms of pathological lesions were brought about. In the athletic heart, in consequence of great exertion, there had been a large demand for nutritive material by the muscle fibers, and they underwent physiological hypertrophy at the expense of the intermuscular connective tissue. Stop the exercise and the muscle fibers atrophied, but without corresponding hypertrophy of the intermuscular fibers. Hence, a weak heart resulted, the cavities dilated, and sudden death often occurred without apparent reason.

In reference to the athletic heart Mr. Riddle of England has the following explanation of degenerated heart muscle: "Like every other muscle, if given more work, it increases in size. New fibers are formed, the walls become thicker, and the power of the organ is increased, so that it may supply the amount of blood the muscles demand. As day after day this demand falls on the heart during training, runs, etc., the heart, unless the athlete breaks down, becomes more and more powerful. Naturally no harm results from this condition, for the whole output of strength available is constantly being used. When, however, through force of circumstances or advance of age, the athlete gives up periodic training and its accompanying demand on his heart, there is no longer any use for the extra heart fibers. Therefore, just as any other muscle will deteriorate and may undergo fatty degeneration if not fully exercised, so the hypertrophied heart of the athlete undergoes changes which leave him below the normal in heart efficiency when once he has begun to go down the hill of old age.

We now pass on to a consideration of individuals from the fortieth to the fifty-fifth year, the so-called middle-life period. A noted athlete has lately made the following observations in regard to life in the cities: "The New Yorker wants bottled stuff to cure him; he hasn't time for exercise. Let a doctor tell a man to take exercise to cure his rheumatism or gout or neurasthenia or any of those ills that the golden drug brings on, and he'll call the doctor a fool and demand pills or bottled drugs that will cure him while he sleeps. It would take too much time away from the desk or store to exercise."

Dr. F. Gelsbock reports as the result of experiments that a low blood pressure after muscular exertion, such as climbing stairs, is often due to some affection of the muscular substance of the heart. Arteriosclerosis may result from long continued high blood pressure, or conversely, high pressure may be caused by diffuse sclerosis of the arterioles. Among persons with remarkably high blood pressure was a group of men over forty years of age, presenting the appearance of florid health. They were corpulent, prosperous, and active in business, but were under great responsibilities and mental strain.

The three things to relieve hypertonia according to Dr. L. F. Bishop are: A restricted diet, physical exercise, fatigue of the voluntary muscles will relieve or relax the involuntary muscles of the blood vessels; and the third is relief from mental strain. Kisch concludes that the pulse tension, taking into account the maximum tension when the body is at rest and comparing it with that during the performance of a certain work, furnishes a measure of the degree of resistance present in the arterial system in arteriosclerosis and of the reserve energy as well as the functional capacity of the heart.

The physical tests in the United States Navy for the officers show plainly the opinion regarding the ability of men in middle life to take exercise. Many believed that such tests would be a great danger, but the results have shown that the officers have kept themselves in pretty good condition.

It is reasonable to suppose that myocardial disease was responsible for the death of Edward Hanlon, the oarsman, who died at the age of fifty-two after a two-day's sickness of pneumonia. Hanlon is said to have been the most graceful oarsman who ever pulled an oar. He rowed in two hundred races, and held the record for a four-mile row. As one of his old opponents said to the writer, he actually rowed the other man blind. It was known to be a fact that he took no exercise whatsoever for ten years preceding his death.

Before concluding this division of our subject I would like to report briefly one case lately seen in consultation which illustrates our point.

Mr. C., age 52, bookkeeper, was always a man of very good habits inclined to be athletic. Said he never drank to excess. Indulged in a moderate amount of exercise up to 1896 when he took to riding the wheel. He became a very good rider, and like many others during that period, reeled off his century every once in a while. This he kept up till about two years ago, when the bicycle fad ceased. His wheel was put away, and likewise his desire to take any more exercise. He bought an exerciser which he used a little on rising in the morning. After letting up on the severe exertion he noticed that he desired a glass of beer several times through the day. This desire increased until he became to be known for his ability to consume beer. As his weight did not increase he felt that it was not doing him any harm, for the same reason he believed he did not require much exercise. With his desire for beer the smoking habit also grew on him. One evening he was suddenly taken with great shortness of breath upon walking up a gradual incline. The next morning upon getting out of bed he was seized with his first attack of angina pectoris. Diagnosis: Myocarditis, dilated heart, arteriosclerosis, including the coronary arteries.

The lesson to be learned in a consideration of those cases is continued exercise beyond the fortieth year; once an athlete always an athlete. The penalty of early athletics is athletics all of one's life. To lay aside athletics and exercise is to invite tissue changes in the vascular system, particularly the heart and arteries.

Men beyond the fortieth year are a community's greatest asset. They are at the head of all great enterprises, they are the individuals with big ideas and who put through big schemes; they are our engineers, inventors, bankers, incorporators, professors, and successful professional men. We, as physicians, should try and study this subject so that we may prolong these valuable lives instead of allowing ordinary laymen to direct men regarding their health. Who has not heard of our great statesmen putting themselves in the hands of crude trainers and ex-trainers of prize fighters? Without medical knowledge and training the general results cannot be good, except for the fact that these men need exercise as a rule and need it badly.

We now pass on to the period beyond middle life

up to old age. This is the period where one finds a good many conflicting opinions, but the evidence appears to be in favor of regular exercise and plenty of it up to old age, especially if one has been active in early and middle life. H. Toeppen (*N. Y. Med. Jour.*, Feb. 2, 1907) mentions a man in Holland who was seventy when he won a well-contested skating race. Also a man past seventy who came in ninth in a three hundred and fifty mile race which occurred in France a couple of years ago. He sums up by stating that it is futile to try and lay down general age limits for the different kinds of athletic sports. One of the most remarkable feats for an aged man ever recorded is the great performance of Edward P. Weston, who at the age of seventy walked from New York to San Francisco in one hundred and five days. One year prior to this he walked from Portland, Maine, to Chicago, averaging nearly fifty miles a day and covering 1,200 miles. Weston has been an athlete all his life, as in an interview with a reporter he said he exercises every day excepting Sunday. His habits have always been good and he is a strict temperance man.

The recent death of Professor Lombroso at the age of seventy-three calls to our minds that he was a famous bicyclist and frequently journeyed through Europe on his wheel.

The death, a short time ago, of Joss Radcliffe recalls a wonderful feat which he performed at the age of forty-two. He backed himself to run, swim, row, ride a horse and a wheel each a quarter mile within a quarter of an hour. The times he made were: Rowing, 1:43; swimming, 5:39; fastening on shoes, 0:53; running, 1:53; cycling and riding horse together, 2:40; total time, 12:48.

Last year a pedestrian named Hughes, it is said, walked fifty miles in ten hours. His age was stated to be sixty-eight.

In commenting on the death of William Blaikie, lawyer, athlete, and author, a writer states that there was something sadly significant in his death at the age of sixty-one. Mr. Blaikie when young and in middle age was very much interested in athletics. As he grew older he devoted about all his time to his law practice, and it is said that he took no exercise the last year of his life. The strain caused by a very important law case is supposed to have paved the way for a fatal stroke of apoplexy. So interested was he in this case that he frequently worked far into the night on the papers. Here is another illustration of a man who did not keep up his heart muscle, as it is very evident that degenerative changes occurred promptly when he ceased taking his usual exercise, as he was a natural athlete up to his sixtieth year. When a young man he was a stroke oarsman in the Harvard crew which defeated Yale in the year 1866. When seventeen years of age he lifted with his hands alone 1,019 pounds. Another feat was walking from Boston to New York (225) miles, in four and one-half days.

All the best authorities appear to believe that walking is the best exercise of all provided it is done in the open air. Blake thinks walking may be prescribed as a therapeutic measure in certain conditions. Dr. Gaskell says: "A good, brisk walk in the fresh air, with free breathing and good style, is as useful a form of physical exercise as any I know."

Conclusions.—1. In summing up all the testimony for and against school athletics the evidence at hand seems to be against such athletic contests; but this may be due to the lack of precautions, as mentioned by the best authorities in England, where more attention has been given the subject. Without those precautions the results must be disastrous.

2. Marathon races for boys and men are to be mentioned only to be condemned. There is no evidence in their favor and really no excuse for them. On witnessing a Marathon race one can hardly keep from saying, "What fools these mortals be." The death of the first Marathon runner as he announced a great victory should have been an object lesson for all time.

3. As medical men we are not particularly interested in the professional athlete, only so far as his life might become an example to the growing young, many of whom seek our advice when about to enter into athletics. There is great chance of injury being done to the heart by violent exercise in competitive games.

4. From the twenty-first to the fortieth year habits of life are apt to be formed and the athlete may give way to the temptations of the table and the glass as his heart muscle cries out for stimulation.

5. After forty degenerative changes are the most likely sequences to an early active life, especially if, as occurs often, the individual becomes sedentary in his habits. As a rule men over forty do not exercise sufficiently to keep up metabolism. One should be on the lookout for high blood-pressure at this time.

6. It is evident that more attention should be given the subject of degenerative changes in the vascular system in men who have passed the fortieth year.

7. As there does not appear to be any limitation of sports in those beyond middle life active exercise should be advised especially in those who have led the athletic life.

8. Walking in the open air with good style is the best exercise.

9. Finally, there is a close relationship between the athletic life and degenerative changes in the vascular system, especially in the heart and arteries, when the voluntary and the involuntary muscles are not kept in tone by regular systematic exercise, particularly in middle life and beyond into old age.

428 Forty-seventh Street.

Diabetic Gangrene.—In discussing this subject Pilcher says that there is no midway course between simple expectant supporting treatment on the one hand, and amputation high up on the other.—*Long Island Medical Journal.*

Subcutaneous Sporotrichosis.—L. Landouzy enlarges on the importance of the general practitioner being able to make a diagnosis of even rare diseases, such as sporotrichosis, which is perfectly curable under proper treatment, but may go on indefinitely if no measures are undertaken to destroy the parasite, and may lead to useless and disfiguring operations. Such patients may be treated for syphilis and a bad prognosis made for final recovery, and the history may lead to the belief in congenital syphilis in the offspring of the patient. The author cites a case of sporotrichosis which had become generalized, there being many gummatous and ulcerative lesions occupying many different locations in the skin. The general health of the patient was good, and she was able to go about her daily work. The large number of lesions contrasted with the excellent general health, many of them being softened in the center. There was no enlargement of the glands. The spores were cultivated on glycerinated gelatin with success, and characteristic colonies developed. The oblong sporotricha send out prolongations which sporulate. By letting the pus fall on the side of the glass tube, colonies are formed which may be examined with the microscope while in the tube. The macroscopic appearance is pathognomonic. The patient was treated with potassium iodide internally and the local lesions washed with iodine solution. Cure was complete in eight weeks. This treatment is specific for the disease.—*La Presse Médicale.*

REPORT OF A CASE OF ACUTE HEMORRHAGIC PANCREATITIS, WITH AUTOPSY.

By JOHN C. CALHOUN, M.D.,
BUFFALO, N. Y.
PHYSICIAN, BUFFALO STATE HOSPITAL.

PATIENT, a male, age 65, single, well nourished (inclined to adiposity), considerable arteriosclerosis.

Previous history is incomplete. However, for the 12 years in this hospital had had no serious illness, although patient stated that for past 4 years had had rather severe colic each autumn. This had never been severe enough to interfere with his routine duties as a kitchen helper. For 3 or 4 days preceding onset, had some diarrhea, but on day of onset was constipated.

December 3, 1909, about 4 P. M., the patient was suddenly seized with a chill, profuse perspiration, extreme prostration, colicky pain in upper part of abdomen, accompanied by persistent nausea and vomiting of watery, bile-stained fluid. The vomitus contained small, finely divided particles and had no bad odor. The character of the vomitus continued the same throughout the attack.

When seen that evening he was in considerable distress, temperature normal, pulse 130, almost continuous vomiting. Abdomen was very much distended, more marked *below* the umbilicus. It was more or less soft, however, and not especially tender on pressure, except in the epigastric region immediately over the pylorus and somewhat to the left. Here it was exceedingly tender, and the least pressure precipitated more vomiting.

Next morning the patient continued the same, although recovered from the initial shock. A slight icteric tinge was discernible on the face and arms. The presence of a small amount of fluid in the abdomen was made out. The vomiting continued throughout the day, but at less frequent intervals, and the epigastric region was less tender. Patient was catheterized; the urine showed no sugar, a trace of albumin, many granular and hyaline casts, and no bile pigment. There was considerable improvement in patient's condition, although the pulse stayed about 120, and temperature rose to 100.6°. He, however, was able to retain a small amount of liquid nourishment, and during the night had three copious bowel movements, the result of several enemata. The nurse reported the stool to be normal in color and consistency.

The next morning, December 5, the general improvement of preceding day continued till about noon, when there were evidences of collapse; pulse became very weak and irregular, the leucocyte count was 13,600. Operation was decided upon and a median exploratory incision was made. As soon as the abdomen was opened the diagnosis was apparent, as the whole omentum was shot full of areas of fat necrosis. A large mass (comprised mostly of the head of the pancreas) was found with a small amount of bloody fluid in the immediate vicinity. Stones were made out in the gall bladder. The tumor was opened, drainage left in and the abdomen closed. Patient died early the following morning.

The autopsy showed an enlarged hemorrhagic pancreas, full of areas of fat necrosis, as indeed were the omentum, mesentery, and preperitoneal fat. The gall bladder contained several small stones. One stone was present in the common duct, about 2 inches from the duodenum and another triangular facetted stone was lodged immediately below the pancreatic duct in the ampulla of Vater, thus showing beautifully how the pancreas could have become infected from bile. The intestines were congested with a few adhesions in the neighborhood of pancreas, but no actual new lymph formation.

The special features of this case were: 1. The general abdominal distension. 2. The small localized area of tenderness and pain in the region of the pylorus and somewhat to the left. 3. The persistent nausea, hiccoughing, and biliary vomiting, without fecal odor. 4. The marked initial shock with succeeding improvement in patient's general condition. 5. The presence of biliary calculi, and especially the position of those in the duct. 6. The markedly swollen and hemorrhagic condition of the whole pancreas, with the large distribution of fat necrosis. 7. The presence of a small amount of bloody fluid in the abdomen. 8. The absence of glycosuria. 9. The occurrence of slight jaundice *early* in the attack. This, according to the literature on the subject, being unusual. (See "Twentieth Century Practice of Medicine.")

I am indebted to Dr. Hurd, Superintendent of the Hospital, for permission to report this case.

URO-URETER FROM NEOPLASM.

By BYRON ROBINSON, B.S., M.D., LL.D.,
CHICAGO, ILL.

URO-URETER from neoplasm occurs with unfortunate frequency. It is mainly observed in autopsy, death occurring primarily from the neoplasm and

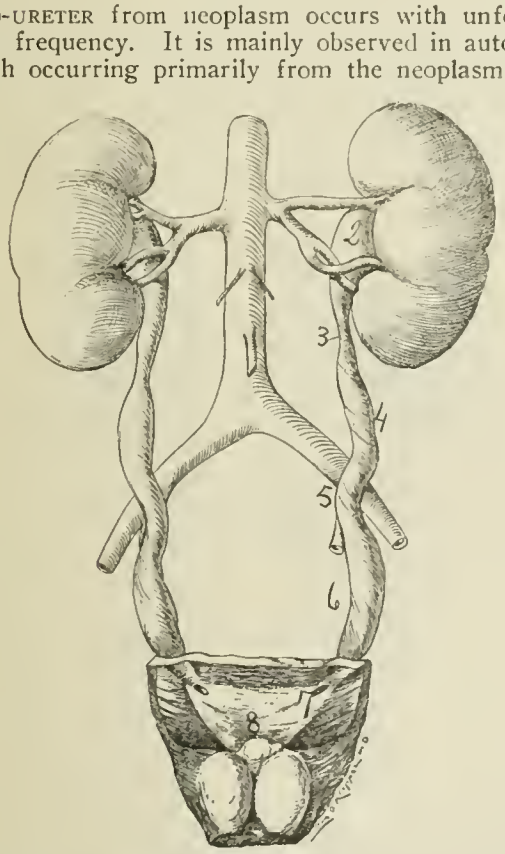

FIG. 1.—This subject possessed marked bilateral ureteral dilatation from prostatic hypertrophy especially for the enlargement of the middle lobe. The 3 ureteral isthmuses (3, 5, 7) and the 3 ureteral dilatations are marked. (Drawn from specimen in Rush Medical College Museum through courtesy of Dr. Le Count).

the uro-ureter being a secondary phenomenon. Uro-ureter may arise from the numerous neoplasms located external to the ureter. First and foremost is the carcinoma from the female genitals. The car-

cinoma closely adjacent to the course of the ureter presents the greatest number of cases of uro-ureter. The inflammatory process accompanying the carci-

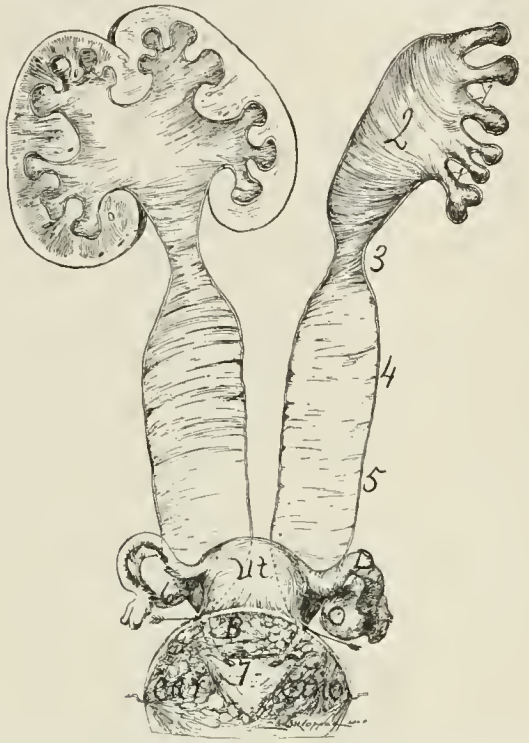

Fig. 2.—Represents an advanced case of erosion by carcinoma of the cervix and bladder. Only the proximal ureteral isthmus remains visible—distention has obliterated all other ureteral isthmuses and dilatations. (Drawn from specimen in Rush Medical College through courtesy of Dr. Le Count).

noma resulting in indurating pariureteritis and cicatricial contraction causes inevitable ureteral obstruction. The carcinoma that radiates from the uterine

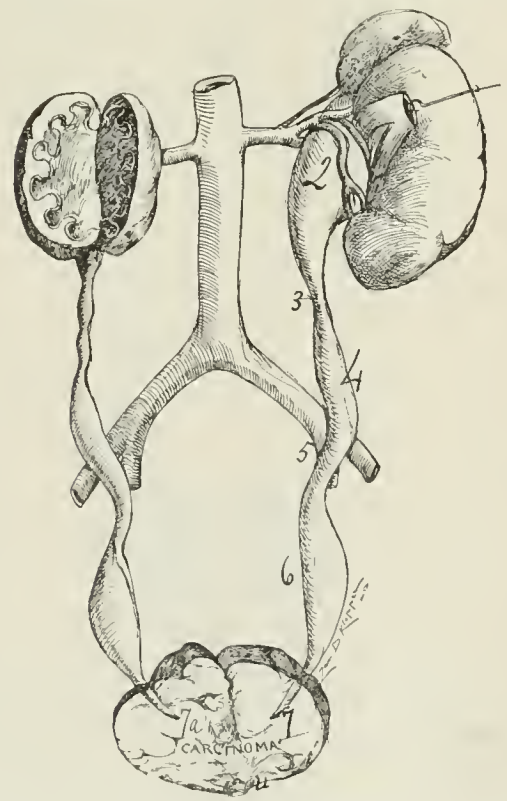

Fig. 3.—This cut illustrates primary carcinoma of the urinary bladder with consequent bilateral uro-ureter. The 3 ureteral isthmuscles (3, 5, 7) and 3 ureteral dilatations (1, 2, 4, 6), are pronounced. The right renal parenchyma atrophic. (Drawn from specimen in Rush Medical Collge Museum through courtesy of Dr. E. R. Le Count).

cervix is the chief cause of uro-ureter; next comes carcinoma of the uterus and ovary, affecting the ureteral lumen by pressure. In carcinoma emanat-

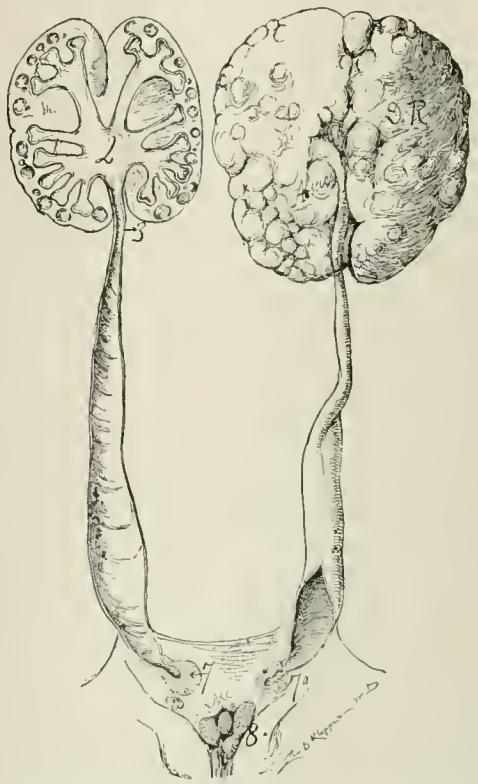

Fig. 4.—This illustration shows a bilateral uro-ureter from prostatic enlargements and orifices of the ureter were solidly and extensively encrusted by phosphatic salts to such a degree that ureteral obstruction was enhanced. The renal cortex in both kidneys were studied with numerous larger and smaller abscesses. The patient was maltreated in the operations. The first operation pretended to incise the perineal portion of the ureter for relief of urinal obstruction—the operator failed to incise the ureter. A week later the operator pretended to perform suprapubic cystotomy but the bladder was not incised; however, the operator entered the peritoneum and the man died from peritonitis. The 3 ureteral isthmuses and 3 ureteral dilatations are not marked. (I secured this specimen at an autopsy with Dr. Charles O'Byrne).

ing from the cervix it is the contraction of the adjacent inflammatory mass on the ureters that originates the uro-ureter, as may be observed in medical

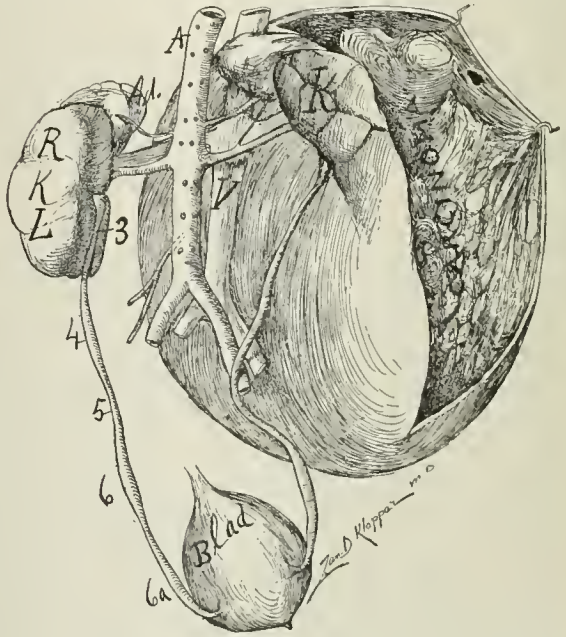

Fig. 5.—This illustration demonstrates the method of ureteral flexion and obstruction by pressure of neoplasm—carcinoma of the kidney. This specimen is from the viscera of a child. (Drawn from specimen in Rush Medical College Museum by courtesy of Dr. Le Count).

museums. Carcinoma of the bladder rapidly causes uro-ureter. Ovarian tumors frequently induce uro-ureter from abnormal pressure. The cellulitis around the ureter accompanying the neoplasm contracts, ending in uro-ureter. Carcinoma of the right colon, left colon, sigmoid, or rectum may be accompanied by uro-ureter. In the male the prostate tells its own story. Extreme angulation of the vertebral column or scoliosis may produce uro-ureter. Israel reports such a case. Uterine myoma might at first sight be thought to be a prominent factor in uro-ureter. However, uterine myoma ordinarily produces slight uro-ureter accompanying gestation. If no peritoneal adhesions accompany the myoma, due to oviductal leakage and peritoneal infection, there is generally but slight uro-ureter as the myoma passes up in the abdominal cavity, where ample space allows the ureter to escape pressure. It must be remembered that gestation and myoma affect the tractus genitalis and tractus urinarius, since both gestation and myoma congest the genitals (through the genital inosculation circle) and the urinary tract (through the solid, compact anastomosis of kidney, ureter, and bladder). Observe that the genital inosculation circle (utero-ovarian artery) is directly connected with the compactly anastomosed urinary organs through the proximal T-shaped ureteral artery emerging from the ovarian artery—hence what congests the genitals (genital inosculating circle or utero-ovarian artery) will congest the ureter at the points where it is connected to the genital inosculating circle by distinct arteries. The genitals and urinary organs are therefore congested during menstruation, gestation, and the existence of a uterine myoma. In conclusion, I repeat that uro-ureter may arise from the compression of a neoplasm located primarily internal or external to the ureter, as *e. g.* carcinoma of the tractus urinarius, genitalis, intestinalis, lymphaticus. It may arise from an osseous neoplasm or from uterine myoma, ovarian tumor, lipoma, or hepatic hypertrophy.

CATARACT OPERATION ON THE INSANE.

By FRANCISCO M. FERNANDEZ, M.D.,

HAVANA, CUBA.

CHIEF OF THE OPHTHALMOLOGICAL CLINIC OF DR. J. SANTOS FERNANDEZ; OPHTHALMIC AND AURAL SURGEON TO THE MAZERRA HOSPITAL AND TO THE SANTA TERESA DE JESÚS SANATORIUM.

In spite of all that has been written about cataract operation, it always offers some especial points of interest. We at the same time have always been interested in the ophthalmic aspect of the insane, and in the short time I have been rendering my services to the Mazerra Hospital for the insane I have had occasion to examine about 200 eye patients. The average number of inmates is 2,200. We have operated upon four cases of cataract; three of the cases were operated upon by the simple extraction method, one was a combined extraction. A general anesthetic was unnecessary in all the cases. We only employed cocaine solution, 3 per cent., one drop every ten minutes up to four drops. All our patients were over 70 years of age. In spite of this, healing took place with rapidity and without any trouble.

The first case was in a negro 90 years of age. During the operation he was quiet, but did not obey well our indications. The extraction was carried out easily, however, and by successive pressures through the lids we were able to expel the cortical remains. The wound healed rapidly, and several weeks after the resulting vision was O. D. (operated) with + 5 sph. v = 1/3

The second case was a failure, for although during the operation the patient remained very quiet, and the operation was carried on perfectly, the patient developed a post-operative delirium and during it she took her bandages off and rubbed her eyes with her dirty hands. The result was a secondary infection and the pupil got clouded. I shall perform an iridectomy on her very soon.

The third case was that of a negro woman. Before operating on her cataract it was necessary to incise an immense pterygium which covered the pupil. This was excised two months before the cataract was extracted. The cataract operation was a success. It consisted in a combined extraction because the pupil was almost covered by the leucoma and an iridectomy was thought necessary. During the operation this patient behaved very nicely, and the resulting vision is very good.

The fourth case was really marvelous, and we have already reported it.* It occurred in an old negro woman who was suffering from senile dementia. She had complete cataracts on both eyes and had the necessity of being led by hand. She was an intractable, mischievous, impertinent old woman, given to fighting with all the other inmates. I operated on her right eye only. During the operation she behaved somewhat quietly, and it was carried out with success. The resulting vision, two months after the operation, was 5/5. The most interesting part of this case was the notable change in the mental symptoms of this patient. She was completely transformed.

Cataract operation can be carried on in the insane. It may be a little more dangerous than in sane people, but not much more. It is evident that extreme vigilance has to be exercised, and one should try to avoid any possible cause of excitation during the operation, and especially during the post-operative treatment.

**Cronica Médico-Quirúrgia de la Habana*, Vol. XXXV, p. 363, 1909.

Stains of aniline dyes may be removed from the fingers with strong aqua ammoniæ.

Acute Intussusception.—In discussing this subject Peterson says: While the diagnosis is easy and the indications for treatment are quite definite, it is a regrettable fact that no class of cases are more habitually mismanaged and more often maltreated than the ones under consideration.—*The Post Graduate.*

Actinomycosis of the Cervicospinal Region.—A. Chauffard and Jean Troisier describe a case of actinomycosis of the side of the neck, which is instructive in its light upon the diagnosis of an unusual disease. The man came to the hospital for torticollis and a tumor on the left sternomastoid region, which was so painful that the slightest movement of the head caused him torture. The diseases that were thought of were Pott's disease of the cervical region and branchioma. In favor of actinomycosis were the following symptoms: extreme hardness of the tumor, trismus, intense pain, rigidity of the neck, condition of good general health, and the fact that the patient was a coachman and in contact with horses, and with straw which he might have chewed, thus inoculating his pharynx. Serum diagnosis was made by sporo-agglutination of Widal, and this was positive in 1-100 dilution. The reaction of fixation was also positive. All cultures remained sterile. The opsonic index was below normal. These tests would indicate the presence of one of the mycoses, sporotrichosis, hemisporosis, or actinomycosis. The clinical characters showed it to be actinomycosis. The treatment was potassium iodide, 4-6 grams per day. Improvement began at once, and the tumor gradually decreased in size, until in about one year the man was entirely recovered and only a slight induration remained.—*Revue de Médecine.*

ANTITYPHOID VACCINATION.

THE most recent announcement with regard to this procedure is that Prof. Elie Metchnikoff of the Pasteur Institute, Paris, has succeeded in inoculating monkeys with the typhoid bacillus, thereby enabling him to obtain exact symptoms, and permitting accurate experiments on the action of his vaccines. Antityphoid vaccination may in the near future take its place as a routine preventive measure, its efficacy in this direction having been demonstrated in a sufficiently clear manner. To Sir A. E. Wright is chiefly due the honor of placing prophylactic vaccination against typhoid on a practical working basis, although Pfeiffer was the first to suggest the possibility of using a prophylactic serum, and Haffkine gained some success in the prevention of cholera by this means. However, Wright was the first to put to practical test the suggestions of others.

Major F. F. Russell, Medical Corps U. S. Army, in Johns Hopkins Hospital Bulletin for March, gives an able résumé of the mode in which the vaccine is prepared and employed, and supplies an account of the immediate results of the administration of 3,600 doses. During the Boer War, Wright furnished 400,000 doses to the British troops and it is reported that 100,000 inoculations were made, but statistics as to the outcome are meager and not to be relied on. Colonel Leishman, after the retirement of Sir A. E. Wright from the British Army, carried on the work and has given the results of the immunization in 5,473 cases. All these cases were carefully watched and the results recorded. Among 12,083 men there were 5,478 inoculated, and 6,610 uninoculated. Among the former there were 21 cases of typhoid with two deaths, and among the latter 187 cases and 26 deaths. Among the exposed troops who had been inoculated with the vaccine in use at present there were 3.7 cases per 1,000 against 32.8 per 1,000 among the untreated. British statistics further go to show that the duration of the protective period is three years, long enough for all reasonable purposes. Antityphoid vaccination in the German Colonial Army in the Herero campaign in 1904 in Southwest Africa was also followed by very encouraging results. Eight thousand men were vaccinated according to the method of Pfeiffer and Kolle, and roughly speaking there were about half as many cases and only about one-quarter as many deaths among the vaccinated.

It is obvious that if vaccination against typhoid fever is effective, or only partially effective, it must be regarded as a necessary procedure in modern armies, especially during war. It would be superfluous to point to the sickness and deaths due to typhoid fever in all modern campaigns. The disease is by far the most fruitful cause of death in modern warfare and any measures that will stay its spread will be gladly welcomed by people and governments. The experiments and tests which have been undertaken and described by Major Russell and his colleagues are therefore opportune and strongly indicated. The vaccination of officers and enlisted men in the United States Army was begun in February, 1909, and up to the present time completed records of the vaccinations of 1,400 individuals have been collected and the attempt has been made to collect statistics as to the immediate results in the way of local and general reactions. We cannot here describe in detail the local and general reactions, but it may be stated that occasionally the local reactions are somewhat severe, though they last but a short time and subside quickly, leaving no scar nor mark of any kind to show where the vaccination has been performed. The general reaction varies considerably. In children and in some adults it is virtually absent. In others there occur chilly sensations with no rise of temperature. Some have diarrhea. The majority express their sensations as resembling grip or a cold, but these pass away quickly. The moderate reactions are characterized by a rise of temperature from 101° to 103° F. and the severe reactions are those with a temperature of 103° F. and above. It was recognized by the army medical officers that if many of such cases occurred, the carrying out of immunization of the army would be greatly hampered, and thus it is satisfactory to learn that severe reactions from vaccination are extremely rare. An interesting point discovered is that the fact that a man may already have had typhoid fever seems to increase the chances of a moderate or severe reaction. That is to say the typhoid fever leaves the patient generally in a hypersusceptible condition. The total reactions recorded by Major Russell and coadjutors is 3,640, of which 0.9 per cent. were severe, 5.7 per cent. moderate, 25.3 per cent. mild, and 68 per cent. absent.

The greatest theoretical obstacle which the adherents of antityphoid vaccination have had to encounter is what is termed the negative phase; that is, that an individual is more apt to contract typhoid fever for a short time after vaccination than he would have been had he not been immunized. Sir A. E. Wright is responsible for the publicity of this belief, which is misleading in that he was not dealing with the effect of the first dose, but with the effect of a dose of toxin on an animal already immunized. It can be demonstrated from the writings of Wright that while the negative phase should not be ignored, neither should it be magnified. Pfeiffer and Friedberger conclude that the fear of a negative phase is exaggerated, and ten years' experience with antiplague vaccination has shown that there is no basis for the hypothesis suggested by Wright, and that experience has shown that individuals can

be vaccinated on the appearance of an epidemic or at any time during its course, and that the vaccination not only does not predispose to infection, but if given during the incubation period actually mitigates the severity of the disease. Indeed the authorities are in conflict with Wright as to a negative phase after vaccination, so that it may be taken as fairly well proven that no such phase exists. Since the introduction of vaccination in our army there have been 135 cases of typhoid fever among approximately 75,000 men, and only one of these was in a man who had been vaccinated.

The following are Major Russell's conclusions: 1. Vaccination against typhoid undoubtedly protects to a very great extent against the disease. 2. It is an indispensable adjunct to other methods of prophylaxis among troops exposed to infection. 3. It is doubtful if there is an increase of susceptibility following inoculation. 4. Vaccination during the disease, for therapeutic purposes, fails to reveal any evidence of a negative phase. 5. The statement that vaccination should not be carried out in the presence of an epidemic is not justified by the facts at hand. 6. The procedure is easily carried out and only exceptionally does it provoke severe general reactions. No untoward results have occurred in the above series of 3,640 vaccinations.

THE ROLE OF CATTLE IN THE SPREAD OF THE PLAGUE.

Plague prevention work continues to be carried on earnestly by officers of the Public Health and Marine Hospital Service in California, and many facts of interest are constantly being discovered. In a recent report to the Surgeon General, Passed Asst. Surg. G. W. McCoy states that an infected ground squirrel has been discovered in San Luis Obispo County, Cal., and goes on to say that about 2,000 squirrels from this county had been examined before an infected one was found, a sufficiently striking illustration as to why the determination of the extent of the epizootic is a matter requiring much time and work.

The most important and instructive part of the report is that which discusses the possibility of cattle as intermediary hosts for squirrel fleas, Asst. Surg. Simpson, after referring to the comparatively easy explanation of the mode of plague transmission from rat to man by the agency of infected fleas, points out the difficulty of tracing an intermediary host in the possible transmission of plague from squirrel to man. Of course, there is no difficulty in understanding how fleas pass from squirrel to squirrel, owing to their close association in their villages, and it has been clearly demonstrated that infected fleas can transmit plague from squirrel to squirrel; but the stumbling block is to be able to account for the method of conveyance and the opportunity for the passage of infected fleas from squirrel to man. The squirrel may obtain, in fact does obtain, a part of his food supply from man, and often lives in a territory traversed by man. In a few words, although, as a rule, the squirrel does not come into such close contact with man as the rat, plague in man has occurred with sufficient frequency where this close association could be shown to warrant the statement that the infection came from the squirrel. But two cases of plague infection of man have occurred, where there was no exposure to rat infection, and where the route of infection could not be traced to the squirrel. Simpson offers as a possible solution that cattle on the range may be a means of the conveyance of fleas, and in support of this theory draws attention to the following facts: Fleas abound in and about squirrel villages, the number present depending on the season of the year, and cattle as they range over this territory stray through and lie down to rest in and around these villages. They might thus very readily acquire fleas, and since it has been established that fleas quickly desert an animal after death and seek another host, they would the more readily acquire fleas in those villages containing infected squirrels. Where fed daily, at some common point, as is the case with dairy cattle, they might readily convey these fleas from the homes of the squirrel to the homes of man, and plague occurring in such circumstances, where this intermediate host was not recognized, would not be satisfactorily traced to its source.

This is an ingenious and a plausible theory, although at first sight it may appear far fetched. It is known that squirrels are prone to plague infection, and two cases of plague in man have occurred in which the link in the chain of infection was not traced, that is to say no squirrels were known to have been near enough to the sufferers to have communicated the disease directly by means of infected fleas. It is, therefore, possible that cattle were the intermediary carriers, although much more will have to be learned on the subject before this explanation can be unreservedly accepted.

Torsion of the Movable Cecum.

Though chronic pain and tenderness in the right iliac fossa, especially if interrupted by intercurrent acute gastrointestinal symptoms, are in the vast majority of cases the result of disease of the vermiform appendix, it occasionally happens that at operation in such cases this organ is found to be quite normal, and that after appendectomy the symptoms continue. In the *Münchener medizinische Wochenschrift* for February 15, 1910, Klose describes a condition which he calls chronic torsion of the movable cecum, which he believes to be responsible for a certain number of such cases. He states that in from 10 to 23 per cent. of all cadavers it is found that, as a result either of previous inflammation or of a congenital anomaly, the mesocecum is greatly elongated and the cecum abnormally movable. Under ordinary circumstances this causes no symptoms, but if, as a result of numerous pregnancies, infectious diseases, or tight lacing, the cecum becomes atonic, trouble may occur, and if the organ develops a tendency to twist on its mesocecum serious and even fatal results may follow. Such attacks are characterized by colic, intermittent or associated with more or less continuous pain. The temperature is normal or subnormal. The attacks occur with increasing frequency, are preceded by marked constipation, and closed by a foul diarrhea. Changing of position often brings rapid relief. On gentle palpation in the right iliac fossa an elastic mass the size of a small apple is felt, which may be moved

about, even beyond the middle line of the abdomen, and under firm pressure may disappear entirely. On palpation loud borborygmi are heard. Such a tumor mass, associated with absence of fever, is the most characteristic sign of the condition. In severe cases acute obstruction may occur, and unless this is relieved death may result. The treatment consists in immediate laparotomy and anchoring of the cecum in its proper place.

Syphilitic Nephritis and the Effect of Antisyphilitics on the Kidneys.

Syphilis is a general infection that affects every organ of the body to which the treponema can find its way. The kidneys are spared no more than the other internal organs, its effect on them being rapidly disastrous in some cases, while in others it is not seen for many months or years. In the secondary period of the disease we find a form of nephritis occurring in which there is marked and sometimes suddenly appearing edema, a very large amount of albumin in the urine, and a normal amount of urine passed. In this form death with uremia or edema of the lungs speedily occurs. In the tertiary stage various forms of kidney involvement are found which may continue for a long time without serious symptoms intervening. Whether the treponema is to be found in these kidneys has not as yet been ascertained. It has been detected in the urine in such cases, but the microorganism may have passed into the urine from lesions of the genital or lower urinary organs. A. Gouget in the *Gazette des Hôpitaux*, for November 18, 1909, advocates the use of the ordinary mercurial and iodide remedies for the kidney conditions, pushed rapidly to their physiological effects. On the other hand we have records of fatal cases of mercurial intoxication due to the effect of the drug, which is eliminated through the kidneys. The overworked organs underwent an acute nephritis with fatal result. Charles Vandenebeele, in *Le Nord Médical*, for February 15, 1910, gives it as his opinion that when we get a nephritis in a manifestly syphilitic subject and mercurial treatment has caused improvement in the kidney-symptoms, we may conclude that the nephritis was due to the syphilis and not to the mercury. Gottheil in a paper read at the annual meeting of the American Medical Association, for 1909, gives histories of two cases in which the use of too large doses of iodide of potassium caused death from iodide intoxication due to its effect on the kidneys. This drug is also eliminated by the kidneys. There seems to be a necessity for caution in the administration of these drugs in case of syphilitic involvement of the kidneys.

News of the Week.

A Bust of Horace Wells in Paris.—A marble bust of Horace Wells, the American dentist who in 1844 made the pioneer experiments in the use of nitrous oxide as an anesthetic in dental surgery, was unveiled in Paris on March 27 in the Square des Etats Unis by the sculptor, M. Bertrand Boutée. It bears the inscription: "A Horace Wells, novateur de l'anesthésie chirurgicale." All the members of the Dental Institute attended. Addresses were made by Deputy Georges Berry, Prof. Dastre of the Academy of Sciences, and Dr. Jenkins, President of the American Dental Club in Paris. The latter speaker expressed the gratitude of the American people "to generous France, which was the first to acknowledge the importance of his discovery and now raises an enduring tribute to his memory."

The Cartwright Lectures.—Professor Magnus-Levy of the University of Berlin will deliver the three Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons of Columbia University at the New York Academy of Medicine, 17 West Forty-third street, on April 11, 12, and 13, at five o'clock in the afternoon. The subject of the lectures will be "Some Phases of the Chemistry of Diabetes." All those interested are cordially invited to attend.

Chronic Leprophobia.—For the past sixteen months Miss Mary V. Kirk, of Aiken, S. C., has been quarantined at her home in that city for leprosy acquired three years ago while serving as a missionary in Brazil. It has now been voted by the city council of Aiken to build a special cottage for her permanent isolation, to pay her for her own house, which will be confiscated and destroyed, with all its contents, and to allow her, in addition, a specified sum annually for the remainder of her life, or until such time as she may be considered by competent authority as cured.—*Boston Medical and Surgical Journal.*

A Fellowship in Pathology at Mount Sinai.—This hospital announces the establishment of a second fellowship in pathology which will be known as the Eugene Meyer, Jr., Fellowship. The income of the new fellowship, like that of the George Blumenthal, Jr., Fellowship, which was established in 1908, is $500 per annum. All graduates in medicine are eligible. The term of appointment is one year, renewable at the option of the committee, consisting of Drs. A. Jacobi, A. G. Gerster, F. S. Mandlebaum, and E. Libman. The work done under these fellowships may be carried on either in Mount Sinai Hospital or elsewhere, under the direction of the pathologists of the hospital.

State Investigation of Hysteria.—The State Lunacy Commission of New York has announced that a systematic study of hysteria will be begun in the State Hospital under the jurisdiction of the commission. A review of all the cases now in the institution will be made. The work is due to the methods and studies introduced by Dr. Adolph Meyer, retiring director of the Pathological Institute.

Department of Public Health.—The bill prepared by Senator Owen providing for a Department of Public Health, the chief of which is to be a secretary with a seat in the President's cabinet, has been introduced in the United States Senate.

Typhoid Fever in Chicago.—This year the typhoid fever mortality in Chicago has been very much lower than during the corresponding period last year. From January 1 to March 19, 1910, the deaths from typhoid numbered 51, as against 83 for the corresponding weeks in 1910.

The American Society for the Study of Alcohol and Other Narcotics will hold a meeting April 6 and 7, 1910, at the Hotel Rittenhouse, Philadelphia, Pa. Sessions will be held each day in the afternoon at 2 and in the evening at 8.

University Clinic at Yale.—At the meeting of the Yale Corporation, recently, announcement was made of an anonymous gift of $25,000 for the endowment of the University Clinic. The fund will be used for the Yale Medical School and the New Haven Dispensary.

New Stamford Hospital.—The sum of $35,000 has been donated by Mr. Albert Crane for the purchase of a site for the new Stamford Hospital to be erected in Stamford, Conn.

The Pasadena Hospital has received a gift of $5,000 to endow a free bed in the children's ward from Miss Margaret Carnegie, the daughter of Mr. Andrew Carnegie.

The German Baptist Hospital Association of the Two Dakotas was formed at a meeting held at Emery, S. D., recently. The purpose of the association will be the establishment by the Baptist Church of a large hospital to draw from both North and South Dakota. The present hospital at Emery will be purchased by the association.

Professor Magnus-Levy of the University of Berlin will arrive in New York on April 4. He comes to deliver a lecture before the Harvey Society on April 9 at the Academy of Medicine and will also give the course of Cartwright Lectures of the Alumni Association of the College of Physicians and Surgeons. He will be at the Hotel Manhattan for a few days after his arrival in this country.

Charitable Bequests.—By the will of the late Anna D. Evans of Philadelphia the sum of $5,000 is bequeathed to the Germantown Hospital for the endowment of a free bed to be known as the Thomas Walls Evans and Anna D. Evans Memorial. By the will of the late Emma Shive of Philadelphia the sum of $500 is bequeathed to the Methodist Hospital, and a like sum to the Philadelphia Home for Incurables. By the will of the late Martha A. Hance of Philadelphia the sum of $1,000 is bequeathed to the Children's Homeopathic Hospital.

The Seventh District Medical Society of Georgia held its semiannual meeting at Dalton, Ga., March 10, 1910. The following officers were elected: *President*, Dr. J. P. Bowdoin of Adairsville; *Vice-President*, Dr. T. S. McLain of Calhoun; *Secretary and Treasurer*, Dr. H. L. Erwin of Dalton.

The Louisville Society of Medicine was incorporated recently in Louisville, Ky. The membership is to be limited to thirty physicians who must be residents of the city.

The Pawtucket (R. I.) Medical Society, at a meeting held March 17, 1910, elected the following officers: *President*, Dr. Byron U. Richards; *Vice-President*, Dr. A. R. V. Fenwick; *Secretary*, Dr. Charles H. Holt; *Treasurer*, Dr. M. A. Ford.

Dr. Oliver Morse Dawing.—At a stated meeting of the medical staff of the Long Island State Hospital, held March 22, 1910, the following resolutions were adopted: "*Whereas*, It has pleased an allwise Providence to take from our midst our beloved superintendent, Dr. Oliver Morse Dawing, who passed away after a week's illness of lobar pneumonia on March 15, 1910. *Resolved*, That the medical profession has lost a valued member, the State hospitals an able and efficient superintendent, the members of the staff a valued friend and colleague, and the patients under his supervision a sympathetic friend, whose genial good nature added much to their happiness and the betterment of their condition. *Resolved*, That we desire to express to the family our sincere sympathy in this hour of sad bereavement, and *Resolved*, That a copy of this resolution be sent to the family, also for publication in the medical journals, and that it be filed with the records of this hospital."

Obituary Notes.—Dr. Willis A. Barclift of Hartsells, Ala., died at his home March 14, 1910, aged 57 years, as a result of an operation. He was a graduate of the University of Tennessee in 1878. He was a member of the Morgan County Medical Society and the Medical Association of the State of Alabama.

Dr. Charles B. Richards of Binghamton, N. Y., died in St. Petersburg, Fla., March 6, 1910. He was a graduate of the Cleveland Medical School in 1852.

Dr. Henry D. Rosenberger died at Manheim, Pa., on March 17, at the age of 58 years. He was graduated from Hahnemann Medical College of Philadelphia in the class of 1875.

Dr. Elmer K. Schaub died at Lancaster, Pa., on March 15, at the age of 40 years. He was graduated from the Medico-Chirurgical College in the class of 1902.

Dr. George H. Rodgers of Hammond, N. Y., died February 5, 1910, aged 49 years. He was a graduate of Hamilton College in the class of 1883, and of the University of the City of New York, class of 1888.

Dr. Homer O. Bates of Long Beach, Cal., formerly a practitioner in Chicago, died at Sierra Madre, March 10, 1910, aged 64 years. Dr. Bates was a graduate of the College of Physicians and Surgeons of Keokuk in 1878, and was a member of the Los Angeles County Medical Society, the Medical Society of the State of California, and the American Medical Association. He was the first president of the Long Beach Medical Society.

Dr. George T. Blynd of Berlin, Wis., died March 18, 1910. He was a graduate of the Northwestern University Medical College in 1904.

Dr. Louis Drucklieb of New York died at his home, March 22, 1910, aged 54 years. He was a graduate of the College of Physicians and Surgeons of New York in 1886.

Dr. Raymond B. Harris of Savannah, Ga., died at his home, aged 71 years. He was a graduate of the Savanah Medical College in 1859, a veteran of the Confederate army, and a former State Senator.

Dr. John B. Laidley of Conway, Mass., died at the Franklin County Hospital, on March 18, 1910. He was a graduate of the Long Island College Hospital in 1883.

Dr. Welton O'Bannon of New Madrid, Mo., died at his home March 16, 1910, aged 56 years. Dr. O'Bannon was a graduate of the Medical department of Washington University in 1875. He was a former president of the New Madrid County Medical Society and a member of the Missouri State Medical Association. Dr. O'Bannon was for sixteen years the Mayor of New Madrid.

Dr. John J. Saville of Chicago died in Omaha, March 11, 1910. He was a graduate of the University of Pennsylvania in 1862 and a veteran of the Civil War. For many years Dr. Saville practised in Omaha and at one time was Health Officer of that city.

Dr. James S. Spiller of King William, Va., died at his home March 12, 1910. He was a graduate of the University of Maryland in 1870.

Dr. Ralph M. Cole of South Boston, Mass., died at his home March 12, 1910. He was a graduate of the Harvard Medical School in 1883, and was a member of the South Boston Medical Society, the Suffolk County Medical Society, and the Massachusetts Medical Society.

Dr. Herman M. Sorin of Camden, N. J., died

of penumonia on March 22. He was graduated from Jefferson Medical College in the class of 1904.

Dr. Albert Ellershaw, formerly of Bridgeport, Pa., died at his father's home in Blackpool, England, on March 25, 1910. He was graduated from Jefferson Medical College in the class of 1891, and was a member of the Montgomery County Medical Society and the Medical Society of the State of Pennsylvania.

Dr. Sidney Bishop of Bridgeport died at his home, March 24, 1910, aged 58 years. He was a graduate of the Bellevue Hospital Medical College in 1873, but had never practised his profession.

Correspondence.

DR. MEYER'S CRITICISM OF THE METHOD OF CONTINUOUS INTRATRACHEAL INSUFFLATION.

To the Editor of the Medical Record:

Sir:—When I invited Dr. Meyer to discuss my paper before the Academy of Medicine on our method of intratracheal insufflation, I did it with the full expectation that he would criticise our method adversely. Nevertheless, I was greatly surprised on hearing his discourse and still more so in reading the authentic version of it in the issue of the Medical Record of March 13. The character of Dr. Meyer's criticism and the manner and spirit in which it was presented are a genuine disappointment to me. I would have preferred not to enter into a discussion of this kind of criticism, leaving the fate of our method to the impartial test of men endowed with a judicial spirit. However, Dr. Meyer's standing among surgeons and his creditable work in behalf of intrathoracic surgery in this country make it impossible for me to let his criticism pass unnoticed. In the following lines I intend, therefore, to shed some light on the scientific merits of Dr. Meyer's argumentation.

At the onset I wish to point out the contrast between the two papers. In my paper I reported briefly facts established in a great number of experiments in which the efficiency of a certain principle in artificial respiration was tested in a variety of ways. I did not discuss the practical efficiency of any other method nor did I draw the conclusion that on the strength of our experiments surgeons should apply our method in their operative work on human beings. I only made the suggestion that surgeons who have the opportunity should test this method on animals and then judge for themselves whether and when it may be applied to human surgery. I was entitled, however, to speak with favor of the method since it was already tested by such surgeons as Drs. Carrel and Elsberg, who, on the basis of their own extensive experience, are in full accord with my view of the efficiency of the principle involved. Dr. Meyer did not discuss the paper which I presented, but read a paper which was prepared previous to his hearing of mine and in which he assails our method and "apparatus" in all sorts of ways.

Did Dr. Meyer test our statements and find them to be untrue or find the method to be inefficient? Nothing of the kind! Dr. Meyer's paper, which is even longer than mine, contains practically not a single fact; it consists merely of theoretical arguments which could have been written up by any person who had some fragmentary knowledge of our method from hearsay. Dr. Meyer cannot speak of the demerits of our method from personal experience. He has never tested it personally. He has seen the experiment four times while I carried it out, twice while the experiment was still in a transitional theoretical stage, and twice in its present shape. The experiments came off every time without a hitch. Thus while we offered well-established facts tested and confirmed by unbiased third parties, Dr. Meyer offers an intemperate criticism solely on the basis of general considerations.

Before analyzing the merits of Dr. Meyer's theoretical objections, I may be permitted, for the sake of a better understanding of what is to follow, to restate in a few words the essentials of our method. A rubber tube is introduced into the trachea to the bifurcation and a continuous stream of air is sent through the tube, which continuously returns through the space between the tube and the tracheal wall and escapes through mouth and nose. When the size of the tube is in a certain favorable proportion to the size of the trachea, the life of the animal remains normal, even if the respiratory movements are completely abolished by one method or another. But even when the proportions between the sizes of the tube and trachea are less favorable, the respiratory movements can be completely dispensed with, if the continuous stream is occasionally interrupted. We found, among other points, that while using this method no mucus accumulates in the trachea, that nothing can enter into the trachea from the pharynx, and that no death from ether occurs—all on account of the presence of the continuously returning air stream within the trachea. We shall now take up the adverse criticisms advanced by Dr. Meyer, which extend to a variety of issues—our rights to the method, its name, characteristics, shortcomings, dangers, etc. We shall discuss them one by one—at least most of them.

As to the name, we designated our method as continuous intratracheal insufflation. Dr. Meyer introduces his criticism with the statement that for the "purposes of this (his) paper" he will call it the "blow-pipe method." Why "blow-pipe"? The Century Dictionary has the following: "Blow-pipe—an instrument by which a current of air or gas is driven through the flame of a lamp, candle, or gas jet to direct the flame upon a substance, in order to fuse it, an intense heat being created by the rapid supply of oxygen and the concentration of the flame upon it." Can anyone outside of Dr. Meyer and his advisors see the reasonable connection between a blow-pipe and our method? Besides, Dr. Meyer might have had the courtesy of permitting the parents to name their offspring—even if it be desirable to choke off the life of the latter while it is still in its infancy.

Dr. Meyer begins his attack upon the insufflation method by stating that "Robinson and Kuhn, each separately, but considered in conjunction, certainly have already done what it is proposed to do in the blow-pipe method." Assuming that this statement contains the truth—how does this claim make the insufflation method inefficient? Is Dr Meyer's paper intended to criticise the method or to attack the men who advocate it? As to the truth of Dr. Meyer's assertion, I have to say the following: With reference to Robinson, I have given him in my paper as much credit as is due him. I can only regret that he gave up his investigation in the right direction, to which he was stimulated by a communication of Sollmann on the Hirsch (Volhard) method. I am still more sorry for Dr. Robinson's present inimical attitude towards the insufflation method, as was manifested in his discussion of my paper. As to the possible claims of Kuhn, the differences between the two methods ought to be perfectly clear to anyone who takes the trouble to understand the points at issue. In our method the cutting out of the "dead space" is an essential point; we insist that the tube should reach the bifurcation, that the air stream should be practically continuous, and that there should be a recurrent air stream within the entire length of the trachea. Kuhn's tube avoids the trachea, and the recurrence of the air stream in Kuhn's method occurs already about the level of the soft palate or thereabout. Dr. Meyer's attitude in this matter is rather amusing. On the one hand (p. 484), he claims for Kuhn the priority to the insufflation method, and on the other hand (p. 485) he claims for Kuhn's method the advantage over the "blow-pipe method" because Kuhn's tube stops at the upper end of the trachea!

Here I may conveniently mention Dr. Meyer's criticism of our claim in favor of the administration of ether by the insufflation method. He compares it with the method of "pulmonal anesthesia" of Kuhn and mentions among the drawbacks of that method that it requires a large quantity of ether, and adds: "The same holds good for the blow-pipe method." In the operation mentioned by Dr. Meyer in his paper, which he performed under the "blow-pipe" method, under my supervision, the quantity of ether which was used up amounted to about one-half of that which is usually consumed in operations of similar length—as I was informed by one of Dr. Meyer's assistants. I have already stated in my paper that a great deal less ether is consumed while using the insufflation method than by any other method. The difference between Kuhn's pulmonal anesthesia and the anesthesia by the

insufflation method is also self-evident, because in this method, as we have stated it, the "continuous returning current of air prevents its too great accumulation in the bronchi and alveoli."

In another place Dr. Meyer asks what provisions are there in the "blow-pipe" method for cases in which an overdose of ether was given? We dealt with this point in our paper; but I shall say here again that the insufflation method is better able to cope with such an accident than any other method, inasmuch as immediately on the removal of the ether it sends deeply into the lungs a continuous stream of pure air, thus accelerating the removal of the lingering ether and at the same time administering very efficiently artificial respiration.

One of Dr. Meyer's theoretical objections to the "blow-pipe method" is that the tube will irritate the trachea and "cause secretion of mucus if not capillary hemorrhage." In support of this he cites Kuhn, who found very considerable accumulation of mucus even when the tube was pushed only one inch below the larynx. We have stated in our paper that we have examined the trachea of many dogs in which the insufflation method was employed continuously for hours and always found the mucous membrane to look dry and normal. I may add that in recent studies of poisoning with large doses of morphine, in which cases there is usually a great deal of mucus in the pharynx, larynx, and also in the trachea, the latter was found to be perfectly free from mucus in all cases in which the insufflation method was employed for some time. Dr. Meyer, who has no observations of his own, has no right to doubt our statements, and as to Kuhn's experience, I have again to call to mind the fact that in Kuhn's intubations there was no continuous recurrent stream of air within the trachea to keep it clean. In connection with the point under discussion, I may state here that Dr. Meyer is rather inaccurate in his quotations. He states (p. 487, footnote) that in my paper I reported an experiment in which I "blew finely powdered charcoal into the afferent air and found very little of it in the alveoli, but most of it deposited on the walls of the flue." In Dr. Meyer's language, the flue means here the trachea. The reader, however, will find in my paper in the MEDICAL RECORD (p. 481) that in this experiment most of the powdered charcoal did not settle on the surface of the trachea, but "was returning immediately in a stream through the mouth and nose as through a chimney." The difference between the two versions is here quite essential.*

In his anxiety to prove that there is nothing new in our method, Dr. Meyer devotes quite a good deal of space to a discussion of some factors in the physiology of respiration for the purpose of showing that in the "blow-pipe method" "the breathing is intermittent, it is the spontaneous action of the lung, and the bellows only serves the purpose of delivering enough air to make the lung stay distended with an open thorax," and "consequently the blow-pipe method appears to be a positive differential pressure system." Dr. Meyer's physiological discourse here is not all very clear to me; however, I need not discuss it. Since with the "blow-pipe method," with or without occasional interruptions, curarized animals continue to live in a normal fashion, it is evident that in this method the breathing is not accomplished by "the spontaneous action of the lung," and it is also evident that the blow-pipe method cannot be identical with "the positive differential system" because in the latter "system" curarized animals die within a few minutes.

Dr. Meyer tries next an excursion into the theories of apnea and states that it may well be that the slowing up of the respiration in the blow-pipe method is due "rather to its harmful influence upon the nervous vagus, harmful because the vagus reflexes affect not only the lungs but also the heart. I have no means of knowing what experiments may have been made by Meltzer to elucidate these conditions. Certainly full light upon them is needed for the use of continuous intratracheal insufflation on human beings." Really, Dr. Meyer ought not to be so exacting in his demands upon our method. If he consults the scientific part of the literature on the "classical" method, he will find (see, for instance, H. Brat. Zeitschrift fur experiment Pathol., IV., p. 244), that the "positive differential system" is in regard to apnea in the same "predicament" as the "blow-pipe method." Nevertheless, surgeons applied the method of overpressure to human surgery not only before "full light" was shed upon the problem of apnea, but even before they guessed that its relations to apnea constitute a profound practical problem. Perhaps Dr. Meyer will permit me to have an opinion of my own in this matter. I have dealt with the problems of the relations of the distension of the lungs to inhibition of respiration and to apnea in original investigations (see Du Bois Reymond's *Archiv für Physiologie*, 1892, and *Amer. Jour. of Physiology*, IX., 1903) long before Luciani published his instructive text book. I take, therefore, the liberty of saying that in my opinion the question of the possible relations of apnea to the insufflation method has no bearing upon the question of the applicability of the method to human beings—notwithstanding Dr. Meyer's emphatic opinion to the contrary. Furthermore, regarding the harmfulness "because vagus reflexes affect not only the lungs but also the heart," perhaps Dr. Meyer will recall that it was at an operation with the "classical" method of positive pressure that I noticed the heart rate becoming very slow, on which occasion I suggested the use of atropine—an innocent measure which completely eliminates the reflexes of the cardiac vagus.

The other objections of Dr. Meyer to our method require less extensive discussion. He says by this method cold air is introduced into the lungs. This is very easily remedied, although, as I have stated in my paper, the importance of the factor of temperature is overrated. He says further intubation is a difficult procedure. To hear it coming from a surgeon like Dr. Meyer is a surprise; at any rate, it is easily learned. Dr. Meyer says the method will not remain so simple as it is now. I agree with him. There are men who will add a trifle to any method, and will make a great deal of it and call it their method. As far as the insufflation method is concerned, I have no objection to any "improvements"; we offer only a principle, not an apparatus. It is for the practical men to see that the method should be applied in a most efficient and at the same time in the simplest way possible. However, some men have no confidence in simple methods. Dr. Meyer seems to belong to this class. He tells with all signs of horror that "at Dortmund, Germany, they have tied a cheap galvanized iron funnel over the dog's snout, connected the tube to a source of compressed air, for inspiration, and for expiration they have dropped a piece of rubber tube into a bucket of water. They opened the pleural cavity and the dog lived. Would you take such risks with a patient?" If this method works invariably well, why not? Would the patient be safer if the funnel were made of gold instead of "cheap" galvanized iron?

Dr. Meyer further contends that the classical type of apparatus is all-sufficient, and under certain conditions it is "a great nerve tonic for the surgeon to operate with the apparatus," while the blow-pipe method and apparatus are of course not all-sufficient. I shall not dispute the first claim and I am willing to admit the last-mentioned contention. Surely there will be conditions in which the insufflation method will prove inapplicable. The method will have its indications and contraindications, but the rules for them will be developed on the basis of sound experimental and practical experience, and not merely on the basis of theoretical considerations, especially not on the basis of such theoretical considerations as were offered in Dr. Meyer's paper.

S. J. MELTZER, M.D.
ROCKEFELLER INSTITUTE FOR MEDICAL RESEARCH.

*Dr. Meyer was inaccurate also in another quotation: On p. 485 I am quoted as having said, twenty years ago, in a discussion, "that with the glottis open, as in intubation, aspiration of foreign matter into the lung was impossible." What I said was that pneumonia, etc., cannot develop while the glottis is open, and not that no aspiration can take place.

THE CURE OF COMMON COLDS AND THE NASAL DOUCHE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the New York daily papers, March 25, 1910, apropos of a meeting at the New York Academy of Medicine the day before, where the advantages of the nasal douche were much vaunted in the treatment of ordinary colds, there was a full report of the proceedings, but no dissenting voice as to the value of the method. To me, this is very unfortunate, since the use of the nasal douche is not infrequently followed by secondary acute pains in the forehead and ears. These pains may be the forerunner

of an acute median otitis, occasioned by the douche. Again, even if this does not develop, subsequently, and after repeated daily use of the douche with salt and water, hypertrophy of the nasal mucous membrane may develop and lead to unpleasant sequels. Formerly, I insisted upon these facts and do not believe there are sufficient and reliable data to change my views.

Beverley Robinson, M.D.

New York.

SPONDYLOTHERAPY IN PERTUSSIS.

To the Editor of the Medical Record:

Sir:—The following simple method has arrested the paroxysms of whooping-cough in a number of patients in from three to seven days: Place a plexímeter upon the spinous process of the seventh cervical vertebra, and strike the plexímeter a series of moderate blows with a percussion-hammer. The number of blows is of little moment, but the blows must be as strong as the child can tolerate without flinching. Some of the mothers accompany the blows with a nursery rhyme or song to interest the child. In the absence of a plexímeter and percussion-hammer, a strip of linoleum and a tack-hammer will suffice. To avoid cutaneous irritation, cotton may be interposed between the plexímeter or the linoleum and the spine. Each seance during the interparoxysmal period should last five minutes thrice daily, and the harmless method may be executed by the mother or nurse. I am desirous of collecting reports on this method of treatment from my colleagues, and to test the efficiency of the treatment it would be well to note the number and severity of the paroxysms before and after treatment in each patient. I shall explain the rationale of the method in a contemplated contribution, and will appreciate any reports sent to me. This method has also succeeded in some cases of laryngismus stridulus.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SLEEPING SICKNESS, SIR D. BRUCE'S RETURN—COUNCIL FOR SOCIAL WELFARE—MILROY LECTURES—INEBRIATES, REPORT FOR 1908—SOCIETIES, VARIOUS—LIVERPOOL INSTITUTION'S GOOD FORTUNE—RED CROSS—OBITUARY.

London, March 11, 1910.

Colonel Sir David Bruce has returned to England on the conclusion of the scientific investigation on sleeping sickness entrusted to his leadership by the Government and the Royal Society. He left for Africa in September, 1908, accompanied by Lady Bruce, who, as on his previous missions, has actively assisted her husband throughout and taken her regular turn in the laboratory work. Mpunu, a desolate spot six miles north of Victoria Nyanza, was the headquarters of the mission, and about the same distance was a concentration and isolation camp where hundreds of victims of the disease were taken to end their days under the care of a Colonial medical officer. In the neighborhood of the headquarters there were at one time fifty churches, but all have been closed, except one, on account of the ravages of the disease.

When Bruce's mission started it was generally believed that the *Glossina palpalis* was infective for only about forty-eight hours. This view has had to be abandoned since Dr. Klein's work in German East Africa. The bearing of this on the plan of removing the inhabitants of fly areas is obvious, as it was supposed that the people could, after a short time, safely return. But that period must be extended for several months at least—at present it is impossible to say how long. The experiments of the commission to determine the period of infectiveness have not decided the point. They collected flies from the lake shore daily, and, so far, all were found infective. Other collections must be made in the zones which have been cleared of population, among which may be named islands in the northern part of Lake Victoria—once densely populated, *e.g.* one island had only 4,000 natives left out of 22,000 formerly living there. This remnant has been removed; other places show equal ravages, and the same measures have been taken. Important work has also been done in tracing the development of the parasite in the glossina.

In the Belgian Congo I hear that there has been a recrudescence of sleeping sickness, which, it was hoped, was becoming less prevalent. The fall in the number of deaths was evidently due to the reduction of the population. During the last decade the native adult population of Kisanto has decreased by 85 per cent. In some villages the children are being attacked to the extent of 25 per cent. The natives are said to be afraid of the treatment by atoxyl, which has been given in some cases until toxic symptoms appeared.

A Council of Social Welfare has been established for London. Such an organization was proposed by the Lord Mayor and the chairman of the County Council some time ago and was formally set up at a crowded and representative meeting on Friday last at the Mansion House. Representatives of nearly all the charitable and philanthropic institutions were present and a large Provisional Council was unanimously appointed. The objects are to strengthen and secure cooperation between social and charitable undertakings throughout the metropolis and to promote the adoption of general principles for this object; to bring into close relations public departments, local authorities, and societies engaged in social service, and to establish councils for these purposes in all the London boroughs. The Charity Organization Society is for the present outside the movement, but hopes were expressed that eventually it would join the new and broader association. Cooperation, coordination, prevention of overlapping are the advantages predicted for this attempt to combine charitable institutions, State aid as recommended by the Poor Law Commission, and every possible mode of alleviating want and distress. It certainly ought to be possible to obtain better results from the seven millions a year spent between the charities and the Poor Law.

Dr. Foulerton, the Milroy lecturer, this year has devoted his course to the streptotrichoses and tuberculosis, a subject on which he has been engaged in the laboratories of the Middlesex Hospital. The investigations there made leave little doubt that cases of streptotrichosis infection are of more frequent occurrence than clinical records suggest, and this apart from cases recognized as tuberculous. Cases are easily overlooked, for although some exhibit clinical peculiarities these are seldom sufficient to determine a definite diagnosis without bacteriological examination. The lecturer's work and that of others in the same direction lead to the recognition of a generic affinity between this class of infections and those passing under the name of tuberculosis. Further comparison of streptothrix organisms and different strains of the parasite of tuberculosis confirm the opinion of those early pathologists who soon after Koch's discovery maintained that his tubercle bacillus was not a fission fungus, but belonged to a higher group of mould fungi. Dr. Foulerton submitted two propositions: (1) That under the name of tuberculosis are commonly included infections caused by more than one species of parasite; (2) that the parasites, generally reported to be bacilli, which are the cause of tuberculosis, belong in reality to a higher group of organisms, and should, as streptothricheæ, be included with the hyphomycetes, or mould fungi. The lecturer pointed out the confusion arising from the various names given to these parasites. In the United States and this country the term streptotrichosis has generally been adopted, though continental pathologists adhere mostly to the older term, actinomycosis. Some writers have referred to these absolutely synonymous terms as if they were of different meaning. In fact, no less than five names have at different times been applied to these parasites.

The position of these organisms in botanical classification, their morphology, and method of reproduction was duly considered in view of the lecturer's purpose to show that the tubercle bacillus has been erroneously placed among bacteria or fission fungi, but its correct position as a streptothrix is among mould fungi.

After referring to saprophytic species, those streptotricheæ which are parasitic and pathogenic for higher plants and animals lower than man were considered. The range of distribution is very great and in passing to the higher animals the fact that most of those known to suffer from the infection are domesticated and herbivorous suggests grain or herbage as the probable habitat of the pathogenic organism.

The report for 1908 of the inspector (Mr. Branthwaite) under the Inebriates Act has appeared as a Parliamentary paper. In a retrospect of the efforts made to suppress habitual drunkenness he has to admit that little if any advance has been made, notwithstanding improvement in the drinking habits of the nation

in general. It is the occasional excess of the man who is usually sober that has become less common, as it is the reverse of fashionable. Capable, thinking men have become more moderate, but there is reason to believe that the "thoughtless incapable who is an habitual drunkard has remained practically unaffected." The mortality of the children of drunkards continues to offer its terrible warning—46.5 per cent. among those of the married and over 59 per cent. of those of unmarried women.

Nothing can be done in these days without an association to promote the object—whether good or bad. Hence some very curious societies are fighting for fads. There is one to prevent premature burial, which inculcates absurd stories of the creepy kind, to the terror of a few ignorant persons. The annual meeting was held on the 24th ult. and to the surprise of most medical men Sir Walter Foster was in the chair.

Another society is devoted to eugenics, which is said to include everything calculated to improve the race. Its members profess to be seriously scientific and its chief object is to instruct the coming generation—the elders being apparently hopeless—by lectures, etc. Mr. Bernard Shaw lately delivered himself on the subject in his usual way. It was amusing enough to hear him poke fun at himself and others. It is otherwise when a serious lecturer addresses young women in a college on the duty of marrying early and choosing partners after the manner of stock breeders.

There are also noisy societies supported by anti-vaccination and antivivisection fanatics. To the latter we are indebted for disturbances caused on several occasions by the fatal gift of the memorial to the brown dog, accepted by the Battersea Borough Council, which has had to be protected by special police. The council on Wednesday determined to remove it and yesterday morning it had disappeared. But the antis seem to have heard of what was to be done and obtained an injunction in chancery extending until to-day. How soon it was served I cannot find out to-day, but it will certainly be a curious position between the council and chancery.

To oppose fanatics the Research Defense Society was formed. The Earl of Cromer is president, and at a meeting a week ago he made an eloquent speech on the right of experimentation. He declared that experimentors were in reality the true humanitarians—not their opponents. He was convinced that every important addition to medical knowledge of late years was due to that method of investigation. Research was precluded from making experiments on living men and therefore claimed the right and duty to do so on living animals. That right seemed to him to be in absolute accordance with the constitution of the world, and, he dared to say, with what one could read, of the divine will.

Mr. W. H. Lever, who was elected in January to succeed the late Sir A. Jones as chairman of the Liverpool Tropical School, has announced the damages awarded to his firm for libel by the Daily Mail and allied papers, amounting to £91,000, will be devoted to the university, the tropical school, and other important public services in Liverpool, and thus show that the motive of the actions was not revenge, but only to defend the firm's rights. The university will be the chief beneficiary.

Yesterday, at a meeting convened by the Lady Mayoress at the Mansion House, a city branch of the Red Cross Society was formed. Sir F. Treves said this country ought to stand at the head of the world in the Red Cross movement, and the Lord Mayor said he hoped the city would have the finest branch of the society. Another branch is to be established in Kensington and a third in Marylebone.

Lieutenant-Colonel J. P. H. Boileau, late of the Army Medical Staff, died on March 4, aged 68. From 1876 to 1883 he was assistant professor of pathology in the Army Medical School, Netley. From 1890 to 1895 he was in charge of the hospital station at Meerut. He retired in 1896. He was M.A. and M.D., T.C.D., as well as F.R.C.S.I., and took the first place in the examination for the diploma in State medicine. He wrote on a number of subjects in the Army Medical Reports.

The death has occurred of Dr. James Rutherford of Dumfries, the eminent psychologist, who was for a quarter of a century medical superintendent of the Crichton Royal Institution. He graduated at Edinburgh in 1863. He was editor and joint translator of Griesinger's Manual of Mental Diseases.

The death took place on Sunday of Dr. G. A. Kenyon, one of the best-known sanitarians. He was medical officer of health to nine local authorities and controlled a considerable area of his county (Cheshire). He took M.B. Lond. with first class honors in 1868.

Dr. John Horne, J.P., died on March 4 at Scarborough, where he had spent fifty years out of the seventy-six to which he attained and where he had held office in the medical charities for much of the time. Last year he founded the "John Horne Homes" for the aged of the town.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 17, 1910.

The Responsibility of the General Practitioner and the Specialist in the Prevention of Deafness.—Francis Patten Emerson goes over some points in the anatomy of the nasopharynx and says that the preservation of hearing as an economic factor can be estimated when we consider that approximately one in every ten persons has normal hearing. He believes that the time is near when all children at stated periods of life will be examined for the prevention of deafness. A large proportion of deafness dates back to the first years of life, at a time when the general practitioner is usually in close touch with the family and could do much to teach them the early symptoms of middle ear involvement and its consequences if neglected. The public should be educated to understand that an earache is not due to neuralgia, teething, worms, or any other indefinite cause, but is a congestion of the middle ear, which needs careful attention. If suppuration has occurred, it is not enough to stop the discharge, but the original cause must be removed, the swelling about the Eustachian tube reduced, and the rhinitis cured. One of the first steps in the prevention of otitis media is a consideration of the problems connected with lymphoid development. Drs. McCollom and Borden of Boston have shown that the middle ear is involved in 10 to 15 per cent. of the cases of scarlet fever; in measles, 18 to 30 per cent., and in diphtheria, 1 to 5 per cent. This is probably high for private practice. In measles and scarlet fever the infection is most active and attended by serious consequences to the hearing function. A discharge from the ear is always a serious matter; some of these ears really never stop discharging. In adults the hearing function is often seriously impaired by the action of certain drugs, notably quinine and salicylic acid. Cryptic disease of the tonsils often has a harmful influence upon the middle ear. This should lead to a careful examination for cryptic disease of the tonsils in all cases in which the serous membranes of the heart, pleura, and joints are affected as well as in such indefinite troubles as rheumatism. No review of the field that does not take into consideration the influence of the kidney, heart, arteriosclerosis, general metabolism, and in fact every organ of the body would be worthy of the science of otology as it is now understood. The aurist must be a practical rhinologist. Otology advances by the help of every worker in general medicine and the allied sciences. The otologist will be fully occupied with the perfection of new operations and many of the procedures now within his domain will become the ordinary routine of the progressive general practitioner.

The Transplantation of Cartilage in the Correction of Deformities of the Nose.—D. Crosby Greene, after reviewing the work done in cartilage transplantation, relates his experience with two cases in which the deformity was the result of undrained abscess of the septum with almost complete destruction of the quadrangular cartilage. An examination of the anatomy of the septum will show approximately the size and shape of the piece to be inserted. A vertical incision was made in one nostril on the septum just posterior to the mucocutaneous junction, as in the usual submucous operation. Through this incision the two layers of mucous membrane which form the anterior part of the septum are separated by dissection. A sharp tenotome used with great care is necessary to avoid perforation. The membranous septum having been separated in the region in front as well as behind, the chamber for the reception of the cartilage is ready. A piece of cartilage which has been freshly removed from another case, washed and placed in sterile normal salt solution, is trimmed to the required shape and placed in the chamber. The wound is closed at its upper part by one or two catgut sutures and both nostrils are lightly packed. In both cases in which Dr. Greene performed this operation there was slight reaction, and the wound healed readily. The profile of the first patient who was operated upon two years ago was greatly improved, but the cartilage had in the

interval been apparently absorbed since it could not be felt. In the second case which had been operated upon two months ago the cartilage had not yet been absorbed. These cases demonstrate that cartilage can be transplanted in cases of destruction of the cartilaginous septum. Although the cartilage may become absorbed it has at least in children the advantage of preventing an increase of the deformity, which, if untreated, becomes more marked with age.

New York Medical Journal, March 19, 1910.

Tuberculosis and Its Treatment by the Administration of Mercury.—Barton Lisle Wright presents certain facts to show that tuberculosis is primarily a systemic infection, a bacteriemia, but never a local condition under any circumstances. Therefore, the terms pulmonary tuberculosis, or tuberculosis of any organ or tissue, are misnomers and are fundamentally wrong, because they are applied to diseases which do not exist themselves, but are only local pathological exhibitions of a constitutional or general systemic infection. Since February, 1908, he has advocated the treatment of this disease by deep muscular injections of mercury. He begins with 1-15 grain of mercury succinimide; gives injections every other day; slowly increases this dose until a slight tenderness of the gums or a slight diarrhea is produced, then reduces the dose until these symptoms are overcome, and continues the injections until thirty are given. Then a rest for two weeks is given, and the treatment repeated. Each series of injections consists of thirty, with two weeks of rest intervening. At the end of one year's treatment a rest of from two or three months should be given when, if the patient is not cured, treatment should be resumed. Patients do better when arsenic is added to the mercury. Good results from this method of treatment have been obtained irrespective of what organ or tissue has shown local involvement. Of the 83 cases treated by this method during the year 1908, 89 per cent. were improved, seven of whom were cured.

The Value and Proper Method of Performance of Auscultatory Percussion of the Heart.—William F. Milroy is firmly convinced that in auscultatory percussion, as he described it, we have a method of ascertaining the outlines of the heart that is superior to all the other expedients recommended for accomplishing that end. The method is summarized as follows: First, place the stethoscope in such a position that it does not rest upon a rib percussed. Second, let the pleximeter finger follow an intercostal space. Third, let the pleximeter finger make uniform pressure at each point where percussion is made, and fourth, to that end and also to abolish the effect of the cushion of adipose tissue in fat subjects, let this pressure be firm so that both ribs bounding the space percussed shall be distinctly felt by the pleximeter finger. Fifth, let the percussion stroke be of very moderate intensity. Sixth, regard the point at which the first appreciable change in the character of the percussion sound is observed as representing the location of the heart. The following conditions may stand in the way of success: Advanced emphysema; extreme ossification of the costal cartilages; a voluminous female breast; a severe acute emphysema; extensive fibrosis of the lungs, pleura, and pericardium; pneumothorax; extensive serous or purulent effusion into the chest cavity; extreme gaseous distension of the stomach.

Plastic Induration of the Corpus Cavernosum.—H. J. Whitacre says that plastic induration is a progressive, painless, connective tissue thickening in the fibrous tissue sheath of the corpus cavernosum which appears in men over fifty years of age and is not the result of local disease in the penis. Two cases of this sort presented themselves to him within the past year, and his failure to contribute greatly to their relief has led him to seek for further information; the literature on the subject furnishes little hope for such cases. The most important symptoms are presented in erection, when a great variety of shapes are possible, often making coitus impossible. The nervous symptoms are quite marked, and suicide may result. No cause is known for the development of this lesion. Therapeutic medication has given no results.

A Case Illustrating the Arrest of Early Paresis.—This case is reported by Tom A. Williams. The fatality of dementia paralytica progressiva is regarded as one of the essentials of the disease and, in the case he reports, certain lessons are drawn; the main one is the necessity of early diagnosis. In this case this was possible through the psychometric examination of the mental functions. Another lesson conveyed by the case is the need of regulation of metabolism during a mercurial course. A third lesson formulated by the case is the need for careful choice of the manner in which mercury should be administered. The drug should be given in injection or inunction. Antispecifics uniformly failed to arrest this disease, he believes, because not sufficient attention has been paid to three causes of failure, viz., too late diagnosis, improper remedies and mode of administration, and lack of attention to the details of bodily and mental hygiene.

Journal of the American Medical Association, March 19, 1910.

Tabes and Iritis.—E. F. Snydacker says that it has been a constant surprise to him that in his experience he has never found traces of former eye symptoms in tabetics. It was only after searching the literature and finding that the same coincidence had been noted by Wernicke in regard to tabes and by Wintersteiner in regard to paresis, that he began to attribute special significance to the fact. He quotes Wintersteiner at some length and mentions his hypothesis that when the ectodermic structures are attacked with predilection by the syphilitic virus the cerebrospinal system is most likely to suffer, but when the mesodermic structures bear the brunt of the attack the iris and choroid are involved and the nervous system escapes. This seems to him hardly a rational theory, and he offers, as better fitting to the case, one based on Ehrlich's theory of the antibodies. If we think of tabes and paresis as due, not to direct syphilitic insult, but rather to the destructive action of antibodies on cord and brain, and if we consider that where antibodies are present in large numbers the likelihood of tabes and paresis is much increased, then, he thinks, the antagonism between tabes and iritis becomes less mysterious. When secondary symptoms are severe, antibodies are largely absent, and iritis is essentially a secondary of syphilis. When, however, the secondary symptoms are kept in check by the antibodies there is imminent danger of later brain disease. It is a recognized fact that tabes, and especially paresis, occur most commonly when there has been little effective treatment used and when there is a lack of secondary symptoms. Many tabetics and paretics deny syphilis, perhaps not even knowing they have had it. As a practical conclusion from the facts, he thinks that we can encourage a syphilitic who has had iritis by telling him that there is a fair probability that he will never have tabes or paresis. The number of cases thus far observed is too small to say positively that a syphilitic who has suffered from iritis or choroiditis will escape tabes, but if future observations corroborate those already made, it will have an important influence on prognosis.

Suppurative Peritonitis.—J. E. Allaben advises for the treatment of suppurative peritonitis the putting and keeping of the patient in the Fowler position, colonic irrigation by way of the cecum, and drainage of the peritoneal cavity. Pus does not itself absorb except under pressure, and in the peritoneal cavity absorption occurs mainly or almost wholly by the peritoneum of the diaphragm which is largely avoided by the above measures. He has employed this method in two cases, one of acute perforating gastric ulcer in which the patient made a good recovery, and the other a case of acute perforating gangrenous appendicitis in which the patient died five weeks after the operation from multiple abscess of the liver due to pylephlebitis involving the ileocecal and portal veins. In neither case was there any attempt on the part of the peritoneum to limit the spread of the infection. The peritonitis in both cases disappeared rapidly after appendicostomy or cecostomy and the above-mentioned measures, though in the one case the pelvis and lower abdomen were full of pus and gastric contents and in the other there was free pus in the abdomen and the cecum had apparently a lowered vitality. The disadvantages of the treatment are given by him as possible leakage of physiological salt solution and feces into the peritoneal cavity, complications from a fixed position of the cecum, and the danger of persistent fecal fistula. As a precaution against leakage he uses a fine catgut suture passed through the serous and muscular coat of the cecum and appendix stump and through the wall of the catheter. The second objection he thinks can be rarely realized, but the fear of a persistent fecal fistula has a more rational foundation. Where the stump of the appendix can be utilized the danger he thinks is less than in cecostomy. With greater experience, he thinks, and with the resulting improved technique, this danger will become less probable. The advantages of the operation are summed up as follows: "1. Large quantities of hot normal salt solution may be rapidly introduced into the circulation, immediately after operation, overcoming shock, quenching thirst, and eliminating toxins. 2. The solution is brought immediately into contact with the portion of the alimentary canal most favorably for absorption. 3. Intestinal paresis due to retention of gases

is avoided and early normal evacuation of the bowels is favored. 4. Early relief of toxemia is secured by drainage through the catheter of bacteria-laden feces. 5 The unpleasant and uncertain features of proctoclysis are eliminated, and predigested foods may be administered in definite quantities."

Cranial Flaps.—A. Werelius and J. J. Moorhead have experimented to ascertain whether or not extensive central flaps for wide exposure of brain can be made with safety, using African rhesus monkeys for the purpose. Very large flaps were cut, including almost the entire cranial vault. In each case the wounds healed primarily and the animals appeared as well as ever. Three experiments of this kind were performed, a small number, but sufficient to demonstrate that large cranial flaps can be made on healthy monkeys without serious danger, and the same would probably be found to be the case in man.

Ether in Cocaine Poisoning.—J. E. Engstadt says that he has had considerable experience with cases of cocaine poisoning, occurring largely in the hands of dentists. In the first few cases he was called on to treat, strychnine and morphine were used in combination, with marked benefit. As cases kept multiplying, however, he found the action of these drugs too slow and it was necessary to find something that would counteract the poison more rapidly when life was in danger. He found this drug in ether administered as ordinarily to produce surgical narcosis. While cocaine inhibits the action of the heart, especially on the right side, and affects also the superior respiratory centers, ether properly given has the opposite effect and has saved what seemed to him hopeless cases. To get the best results it is administered only to the degree of mild surgical narcosis, or even less. Given by the old way it would do harm. A mask should be employed and the ether given by the drop method. This he thinks is all important. It occurs to him that this fact will be of use to others and, just at present since there is so much interest in the work of Jonnesco with stovaine which has a similar effect to that of cocaine, he offers the suggestion of ether as an antidote to this drug also.

The Dyspeptic Type of Chronic Appendicitis.—C. Graham and D. Guthrie have studied that form of chronic appendicitis in which dyspeptic symptoms predominate. They have reviewed carefully the histories of about 200 patients and compared them with histories of ulcer of the stomach and duodenum and gall-bladder disease. Chronic gastric ulcer has a clear cut symptomatology with history usually covering years of complaint in which periods of attack and periods of freedom from symptoms alternate. In the early stages the appetite remains good, nutrition does not fail, and taking food brings immediate relief from all symptoms which again recur about four hours after the meal. Later, the periods become shorter and the nutrition suffers and after complications arise the symptoms change, food may not ease but may increase the distress which is more or less continuous, vomiting is perhaps less frequent but more copious and gives only partial relief and appetite and nutrition fail. Throughout the longer period of the disease, however, the characteristic regularity of the attack is hardly equaled by any other disorder. Gall-bladder diseases have their special symptoms. Four stages are distinguished, based on the degree of their severity. In the very mildest cases there are only slight attacks of distress soon after eating or at irregular times with relief by slight vomitings, eructations, etc., which are often made light of by the patient and sometimes by the physician, though they are just as characteristic as the severer attacks which, as a rule, supplant them. In the second stage, the symptoms are more severe, and the pain may be increased by food, exertion, motion, or deep respiration. When the pain is felt posteriorly it may be called pleurisy. Between the attacks, the health may be apparently excellent. The irregularity of these attacks contrast with those of ulcer. In the third class we find those in which a corrective diagnosis is oftenest made, and surgery is most effective. These are the typical gallstone attacks. The fourth condition is that of chronic gall-bladder trouble, and often chronic gastric disturbances predominate, giving a very similar picture to that of chronic ulcer with complications. The principal thing, however, is to recognize when surgery is necessary. The diagnosis of an abdominal lesion needing surgery is sufficient. In chronic appendicitis in which gastric symptoms predominate, we find a neurotic element in many cases. The patients are usually younger than those with chronic ulcer or gall-bladder disease. The symptoms are irregular as compared with chronic ulcer and prolonged when compared with gall-bladder trouble. The pain is the great symptom; during an attack it often appears after eating. Nausea, distress, flatulence, and a feeling of distension cover the sensations of far more patients with appendicitis than those with ulcer or gall-bladder disease. Location has some bearing, though in all three conditions it may be only epigastric. Here, however, it is often indefinitely epigastric and abdominal. A tender area is often found at McBurney's point, though not complained of subjectively. Food gives no relief, and anything taken into the stomach usually causes more or less distress. The authors consider the common "belly ache" of children as typical appendicitis and a forerunner of later dyspeptic types. Constipation is one of the early symptoms and may be the only one for a considerable period, and discomfort from gas makes more of the general trouble than it does in ulcer, and is referred to by the patient as abdominal largely and is relieved by expulsion. The treatment will hardly bear discussion. In ulcer we have medical cases in the majority, and in gall-bladder disease we may be justified in advising medical treatment, but any advice other than that of recourse to surgery is out of place in chronic appendicitis. In many cases, one can only say that there is a serious trouble in the abdomen, and, if the upper abdomen is found normal on operation, look for the appendicitis.

Berliner klinische Wochenschrift, February 28, 1910.

Senile Phthisis.—R. Staehelin under this name refers to the cases of old people with progressive emaciation and asthenia and without fever, who after having been considered to have died of an internal carcinoma, are found at post-mortem examination to have been the victims of tuberculosis. The diagnosis of such cases is difficult and depends upon the following points: (1) In all cases of chronic disease in old people with subfebrile or even subnormal temperature which do not follow any definite type, one should consider the possibility of tuberculosis. (2) Delay of expansion of one-half of the thorax, even to a very slight extent, indicates the necessity of a very careful examination of the lungs for tuberculosis. (3) Percussion must be by a gentle blow with the finger lying lightly on the thorax, as by this means slight differences of tone are better brought out. (4) On auscultation the patient must be made to breathe deeply and cough loudly, as only by these means may the râles be heard. (5) On suspicion of phthisis an *x*-ray examination of the chest should be made, preferably by means of a plate. In old people especially distinct pictures may often be obtained. (6) Examination of the sputum must be made with much greater care than in younger patients, as in the aged the tubercle bacilli are at times found only with great difficulty. In these cases of senile phthisis it is not necessary to tell the patient the nature of the disease. His relatives should, however, in all cases be informed fully as to the nature of the disease, so that all the necessary precautions which it is customary to take against possible infection of others in the family may be observed.

False Dullness at the Right Apex.—H. J. Bing discusses the cause of this symptom at some length. He summarizes his results as follows: "With marked enlargement of the bronchial glands a false dullness appears at the right apex, weakest internally and more marked outwards. This may be differentiated easily from true dullness (infiltration or retraction) by its position and by means of sagittal percussion, as well as by the accompanying dullness over the chest and back. The dullness at the right apex which one may meet associated with diseases of the nasopharynx, which was first described by Krönig, and which he thought was due to collapse of the lung, is in reality due chiefly, if not wholly, to enlargement of the bronchial glands.

The Treatment of Prostatic Hypertrophy.—Willi Hirt says that he treats the irritative stage of prostatic hypertrophy by the passage of sounds, baths, hot enemata, and diet. Chronic incomplete and complete retention, total acute retention and hematuria, he treats first with aseptic catheterization and bladder lavage. In long standing and severe cases he inserts a permanent catheter. If operation is desired or necessary, the choice according to the severity is resection of the vasa deferentia. Bottini's operation, perineal and suprapubic prostatectomy. Considering the final results, the perineal operation gives better hope of recovery than the suprapubic. The resection of the vasa deferentia is especially indicated in the generally enlarged, soft glands. The Bottini and suprapubic operations are indicated in the cases in which the enlarged middle lobe extends back into the bladder; perineal prostatectomy is of value where the enlarged lateral lobes extend back toward the rectum.

Book Reviews.

Studies in Rabies. Collected writings of Nathaniel Garland Keirle, A.M., M.D., D.Sc. With an Introduction by William H. Welch and a Biographical Sketch by Harry Friedenwald. Testimonial Edition. Baltimore: 1909.

Aside from its personal and scientific aspects this book is chiefly valuable because it contains incontrovertible proof that rabies is a distinct disease and not a mere figment of the imagination, as so many lay persons and a few medical men have the foolhardiness to assert. The existence of rabies is determined mostly by inoculation; for neither the macroscopic nor microscopic appearances are distinctive. The suspected animal should not be killed but confined for something more than 14 days, and allowed to die naturally in order to secure the best evidence possible from brain and spinal cord. In human beings the incubation period is from fourteen days to five years. Any wound supposedly rabic in nature should be treated as follows: Soak in water as hot as can be borne till the doctor comes, who will continue with hot bichloride of mercury 1-1000. Then dry thoroughly. Pack the wound with cotton wool, saturated with carbolic acid. Pack again with cotton wool in nitric acid—a puff of an explosion occurs. Wash with a saturated solution of sodium bicarbonate. Wash with alcohol. Dress dry. This method prevents 50 per cent. of all cases from developing. It should be followed in all strongly suspected cases by antic-rabic injections made from the dried medulla of rabbits. Thus "a greater percentage of those exposed to hydrophobia are prevented by the Pasteur method than by those exposed to smallpox by the Jenner method." The present volume is a valuable addition to the literature of rabies, and brings this subject thoroughly up to date.

Pratique de la Chirurgie Antiseptique. Leçons professées à l'Hôtel-Dieu, par le Docteur J. Lucas-Championnière. Paris: G. Steinheil, Éditeur, 1909.

The author of this book relies rather on antisepsis than asepsis in his surgical work. He claims a wide experience with both methods and cites some extraordinary statistics. He has practised articular surgery, including resection of the knee for many years, and has never seen a case of sepsis. He has sutured the patella "oftener than any other surgeon in the world" and does not take any of the precautions recommended by aseptic surgeons. In 1,135 hernias, inguinal and femoral, he has had only four deaths—two from "pulmonary congestion," one from strangulation, and one from chloroform. To accomplish these ends he uses carbolic acid, hydrogen peroxide, chloride of zinc, boric acid, iodoform, salicylic acid, etc., in fairly strong solutions. In the treatment of miscarriage he permits no lavage before, during, or after the operation. A speculum is introduced, the vagina is sponged carefully with a strong carbolic solution, followed by peroxide of 12-volume strength, the index finger is introduced into the cervix, pressure being exerted with the other hand upon the fundus and the secundines are scraped away with the nail. The fundus is then sponged with a solution of creosote in glycerin, 1 to 10 or 1 to 15. Ordinarily no gauze or other dressing is left in the vagina. Much of the technique the author describes will not appeal to American surgeons.

Ueber die Lage des Wurmfortsatzes. Von Rhaban Liertz, Unterartzt beim 6ten Rheinischen Infantrie-Regiment no. 68, Kommandiert zur Kgl. Charite. Berlin: Verlag von August Hirschwald, 1909.

A very interesting, if not entirely original, exposition of this important subject is presented by the writer in a rather brief but well written monograph. The numerous statistical inquiries on the position of the vermiform appendix in the abdominal cavity have been criticised as being comparatively worthless because they were based on studies on the cadaver, whereas the organ in life is very freely movable. For this reason the present writer based his statistical conclusions on operative findings as well as on autopsy examinations. These include observations on over two thousand cases in a number of hospitals and pathological laboratories. His first series of 97 cases includes examinations on fetuses and young children and presents what is probably one of the most interesting points in the entire monograph, namely that the position of the appendix remains under normal physiological conditions, the same in later life as it was at the conclusion of the embryonal period. At this time the bases for subsequent anomalies of position are determined, such as abnormalities of growth and relation between the adjacent structures, among them the intestine and mesentery. Anomalies of position which occur at a later period are entirely the product of pathological processes depending on an inflammatory or traumatic basis. The writer also investigated the relative importance of McBurney's compared with Lanz's point as a clinical factor in determining the anatomical origin of the appendix and found from an examination of eighty-five fresh bodies that a long needle introduced at the former struck the base of the appendix in only six per cent. of the cases, whereas at Lanz's point eighty-one were reached.

Die Methodische Intestinalpalpation mittels der topographischen Gleit- und Tiefenpalpation und ihre Ergebnisse. Mit Einschluss der Ileocœcalgegend und mit Berücksichtigung der Lageanomalien des Darmes. Von Dr. Theodor Hausmann (Orel). Mit neun Abbildungen im Text und zwei Tafeln. Berlin: Verlag von S. Karger, 1910.

This book describes a method of palpation by which, according to the author, the examining physician is enabled to feel and recognize the parts of the gastrointestinal canal in normal health. The method is founded upon the technique originated by Obrastzoff, a noted Russian surgeon of the last century. Obrastzoff's technique consists in laying the hand upon the abdomen with the fingers at right angles to the part of the intestinal canal to be palpated, and then moving the hand and the skin with it over the underlying structures. The latter then are felt as transverse cords of various size and consistency. The merit of the method can, of course, be judged only by trial and the directions of the book are plain and explicit enough to enable anyone interested in the subject to try the method in practice.

Formulaire Moderne. Traitements, Ordonnances, Médicaments Nouveaux. Par le Docteur R. Vaugaire. Préface de M. le Docteur Talamon., Médecin des Hôpitaux de Paris. Cinquième Edition, revue, corrigée et très augmentée conforme au nouveau Codex. Paris: Vigot Frères, 1910.

The fifth edition of Dr. Vaugaire's formulary consists of an alphabetically arranged list of diseases with the prescriptions and mechanical and surgical procedures, used in the treatment of each affection. The remedies named are not limited to the official preparations, but include such proprietary or patent articles as have been found of use by the author or have been tried and approved by hospitals. The book should prove of interest to American therapeutists desiring to compare their methods of treatment with those in vogue in France. It is well printed and bound, and forms a handy volume for reference.

A Manual of Chemistry. A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A Textbook specially adapted for Students of Medicine, Pharmacy, and Dentistry. By W. Simon, Ph.D., M.D., Professor of Chemistry in the College of Physicians and Surgeons, Baltimore, and in the Baltimore College of Dental Surgery; Emeritus Professor in the Maryland College of Pharmacy; and Daniel Base, Ph.D., Professor of Chemistry in the Maryland College of Pharmacy. New (ninth) edition, enlarged and thoroughly revised. Philadelphia and New York: Lea & Febiger, 1909.

The ninth edition of Dr. Simon's book follows in plan and general characteristics the former editions of this treatise which has been one of the most popular textbooks of chemistry for dental and medical students. The book is divided into seven parts, chemical physics and the general principles of chemistry being considered first; in these chapters additions have been made, electrolysis, ionic theory, and the physical principles of matter being considered from the most modern standpoint. The next two divisions are given up to a consideration of metals, non-metals, and their compounds. The fifth part is given up to analytical chemistry and furnishes a practical guide in laboratory work. Carbon compounds are considered in the sixth part of the book, bodies of importance to medical science being especially noted. The last part of the book is concerned with physiological chemistry and gives in brief the methods used in the clinical study of excretions and secretions of the human body. The book is well illustrated, colored plates showing color reactions, spectroscopic pictures, etc., being especially well executed. A full index accompanies the volume. We willingly recommend the volume as a suitable text-book for students of medicine and dentistry; graduate members of the two professions will also find it of use in brushing up their knowledge of the important subject with which it deals.

Surgical Diagnosis. By Daniel N. Eisendrath, M.D., Professor of Surgery in the medical department of the University of Illinois (College of Physicians and Surgeons). Second Revised Edition; with 574 original illustrations, 25 in colors. Philadelphia and London: W. B. Saunders Company, 1909.

In issuing the second edition of this valuable work the author has subjected the whole text to a thorough revision. Some of it is entirely rewritten, and there is much new matter included. The most important alterations and additions are to be found in the sections dealing with the diagnosis of renal lesions, cystoscopy, and ureteral catheterization; and in the chapter on the head, where the former views in regard to the localization of the motor centers in the cortex of the brain have been replaced by the more recent ideas on the subject. Figures 21 and 22, illustrating the location of these centers, have become inverted.

The Diagnostics of Internal Medicine. A clinical treatise upon the recognized principles of medical diagnosis, prepared for the use of students and practitioners of medicine. By Glentworth Reeve Butler, M.D., Sc.D., LL.D., Physician-in-Chief, Methodist Episcopal Hospital; Attending Physician to the Brooklyn Hospital; Consulting Physician to the Bushwick Central Hospital, and to the Coney Island Hospital; formerly Associate Physician, Department of Diseases of the Chest and Diseases of Children, St. Mary's Hospital, Brooklyn, N. Y.; Fellow of the New York Academy of Medicine; Member of the Medical Society of the County of Kings; Fellow of the Society of Science, Letters, and Art (Lond.), etc. With five colored plates and 272 illustrations and charts in the text. Third revised edition. New York and London: D. Appleton & Company, 1909.

We have two types of books dealing with the diagnostic methods of internal medicine, one serving as works of reference and containing a great deal of polemical and theoretical matter, the other written from the point of view of practical clinical work. Sahli's treatise on diagnosis is a model work of the first type, while the volume before us represents the best of the second type of book. Dr. Butler writes for the practising physician or for the student preparing for the practice of medicine; both meet and study symptoms of disease, and it is these that are considered at length in the first part of the book. These symptoms serve as evidence of special affections and their consideration forms the subject matter of the second part. Part I, accordingly, contains a consideration of the clinical anatomy and physiology of organs and systems under consideration in each case. A description of the approved methods of examination follows. The signs and symptoms obtainable by these methods are then fully considered. Finally, the diseases suggested by these symptoms are considered. All these are treated with such a wealth of illustrations as to make it a special feature of the book. Part II treats of the direct and differential diagnosis of disease. A brief description of the symptomatology is given, and especial attention is paid to all points of possible use in the differential diagnosis. The two parts of the book are complementary to each other and contain practically all that is necessary for the making of a diagnosis. Dr. Butler's book is one of the best works in English in the subject it considers. It forms a most helpful companion to every physician's "Practice of Medicine" and gives information on methods of diagnosis scattered through numerous special works. From the mechanical standpoint and in the matter of charts, illustrations, diagrams, and index, it is likewise excellent.

A Text-book on the Principles and Practice of Surgery. By George Emerson Brewer, M.D., Professor of Clinical Surgery in the College of Physicians and Surgeons, New York. Second Edition. Philadelphia and New York: Lea & Febiger, 1909.

Dr. Brewer's textbook has met with well merited favor and the improvements associated with the second edition will doubtless induce a continuance of this popularity. The second edition means practically a revision of the book, as many things have been added during the last few years to our knowledge of the subject. We are glad to note that the condensation which characterized the former volume has been less adhered to in the present, although even now many important subjects are treated all too briefly, *e.g.* the very short paragraph devoted to lumbar puncture. Color-photography has been employed in a series of interesting plates which show a variety of pathological conditions photographed directly from nature. The majority of the illustrations in the text are of an inferior order and many of them have evidently seen service on numerous previous occasions. Aside from this feature the book offers a concise exposition of the accepted facts of the principles and practice of surgery.

Die Cystoskopie im Dienste der Chirurgie. Ein Atlas cystoskopischer Bilder mit begleitenden Text für Ärzte und Studierende. Von Stabsarzt Dr. O. Rumpel, Privatdozenten für Chirurgie an der Universität Berlin. Mit 85 farbigen Figuren auf 36 Tafeln und 22 Textabbildungen. Berlin und Wien: Urban & Schwarzenberg, 1910.

With characteristic national thoroughness Rumpel has collected his cystoscopic observations of several years and with the aid of Max Queisser, an artist, presents them to the profession in this form. In his short text of 38 pages he assumes that the reader possesses a working knowledge of the cystoscope and loses no time in primary instruction in technique. He reports interesting anomalies of multiple ureters and congenital bladder diverticula diagnosed by the cystoscope and corroborated by radiographs. The text also contains much sound surgical advice. In regard to intravesical removal of tumors, he voices the belief of every surgeon when he says: "There is no doubt that the endovesical method of extirpation can be relied upon only when small pedunculated papillomata are present." In the further consideration of tumor diagnoses by the cystoscope he tritely remarks that "the smaller the tumor the more necessary its precise location," because of the collapse of the bladder walls and the tumor itself during suprapubic cystotomy. More of this sound surgical sense is revealed in his section on prostatic hypertrophy when he says "the smaller and denser the prostate the greater the difficulty of extirpation *in toto*." Under foreign bodies are enumerated the usual list of pins, pencils, etc., then he goes one better by citing a patient whose bladder contained a quid of tobacco. Particularly valuable are his observations in tuberculous cystitis secondary to renal tuberculosis. He presents several plates showing various stages of spontaneous cure of the bladder lesion after removal of the diseased kidney. The cystoscopic drawings are extremely good, and portray Nature faithfully. This book should have a place in every cystoscopist's library, since it is not only an excellent atlas, but will aid the operator in many instances correctly to interpret his findings.

Tumors of the Kidney; Renal, Ureteral, Perirenal, and Adrenal Tumors, and Actinomycosis and Echinococcus of the Kidney. By Edgar Garceau, M.D., Visiting Gynecologist to St. Elizabeth's Hospital, and to the Boston Dispensary, Boston, Mass.; Consulting Gynecologist to the Quincy City Hospital, Quincy, Mass.; Member of the Massachusetts Medical Society, the Boston Obstetrical Society, the Boston Society for Medical Improvement, the American Urological Association, the American Medical Association, l'Association Française d'Urologie, Paris, France; Fellow of the American Gynecological Society, etc. New York and London: D. Appleton and Company, 1909.

In four hundred pages Garceau has presented material which will deeply interest every student of renal tumors. In a clear, occasionally epigrammatic style he views from each standpoint solid tumors of the renal parenchyma, embryonic tumors, renal, pelvic, and ureteral tumors, polycystic and simple cysts of the kidney, peri-, and adrenal tumors, actinomycosis and echinococcus of the kidney. Extensive literary research and the records of the Massachusetts General and Boston Hospitals have supplied abundant statistics, which the author has well tabulated. The preface gives warning of new classifications of renal tumors. These classifications are in general acceptable, but the omission of sarcomata, fibromata, and rhabdomyomata from the growths found in the pelvis and ureter are opposed to the experience of some pathologists. The section on hypernephromata is excellent, containing much of value and interest on the metastases of this growth and trite common-sense directions for physical examination. The chapter on carcinoma, sarcoma, and adenoma, wherein the author presents detailed studies of the case records at his command, is a potent argument for greater care and precision in the classification and nomenclature of malignant renal tumors. The technique advised for nephrectomy is clear, sane, uncomplicated, and conveys the impression of the writer's familiarity with the operation. The closing chapter very appropriately deals with the determination of renal efficiency. The methods herein described are clear, succinct, and comprehensible to those inexperienced in the work. The author follows the pernicious custom of microphotographic illustrations without stating the degree of magnification, instead of the more instructive free-hand drawings.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held March 3, 1910.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Genitourinary Surgery, and consisted in a symposium on stricture of the male urethra.

Causes, Frequency, Pathology, and Complications of Stricture.—Dr. HUGH H. YOUNG of Baltimore read this paper.

Symptoms and Significance of Stricture.—Dr. ALBERT ASHTON BERG read this paper.

Surgical Management and Treatment of Stricture and Its Complications.—Dr. EUGENE FULLER read this paper. (See page 569.)

An Exhibition of Instruments for Internal Urethrotomy.—Dr. WILLIAM F. FLUHRER made this demonstration, and said that the various operations in vogue in the early seventies for tight, deep strictures of the male urethra by external perineal urethrotomy were based upon a liberal incision into the perineum which included all the strictured material, together with some of the healthy urethra before and behind the stricture; consequently such an incision was a very extensive one and in most instances required a long time for healing. Dr. Fluhrer said that he began quite early in practice to reduce the length of such incisions and worked through the perineal incision, cutting the stricture with an ordinary bistoury. It seemed to him not only that strictures could be dealt with mechanically with a small incision through the perineum, but also as a logical conclusion that he might do away with the incision in the perineum altogether; accordingly he worked in the direction of making a more exact internal urethrotomy instead of incising the stricture through a wound in the perineum. If the stricture was cut thoroughly through a small incision through the perineum, one of the chief results would be that it would do away with the risk of a perineal fistula; if one could cut as much and as thoroughly, with precision internally, then the external perineal urethrotomy, mechanically considered, had no reason for being and naturally developed into a pure internal urethrotomy. However, the operation in the perineum had an added advantage; the cut of the knife was a surgical therapeusis, and, therefore, he wished to preserve this feature of the operation. Dr. Fluhrer, with instruments of precision, converted the external urethrotomy into an internal urethrotomy; he also made his cut in the perineum, as in the original external urethrotomy operation, but only to the limited extent in the urethra necessary to introduce a drainage tube, and to preserve for him as well the therapeutic advantages of the incision. This required a systematic kind of an operation, and the instruments which he exhibited should be considered in their relation to the component parts involved in the operation. The first step in the operation was to secure a communication with the cavity of the bladder along the natural path of the urethra. In every case with a tight stricture of the deep urethra permeable to urine he believed this communication could be instrumentally secured. The instruments he used were to be judged not only by the excellent results obtained with them, but by their range as well. There were about fifty urethrotomes in the market, and all had some special point of value. In testing any instrument one should not only judge of the excellent results from its use in given instances, but also the extent or range of its operation should be considered and studied. Dr. Fluhrer then made a presentation of many instruments of original design. The line of communication with the bladder having been secured, the next step was to dilate the stricture. The stricture must be distended to just receive the staff of the urethrotome, but one should make as little divulsion as possible. The caliber of the stricture was enlarged by a tunneled staff and then the instrument he exhibited, which differed somewhat from others in that it was more conical in its shaft, was passed until the tip was in the bladder; it was wedged in the stricture, which had been dilated just enough to receive it. The surgeon then was prepared to incise the stricture under the best mechanical conditions, and the cutting mechanism was run down to the stricture, which was cut. The parts were then drained through a perineal incision. In opening the perineum an ordinary tunnel staff about No. 20 F. was passed down to the point where the urethra was to be opened, then it was reversed in its direction so that its point faced the perineum. Dr. Fluhrer stated that in an active hospital experience of thirty years, affording a large number of tight strictures of the deep urethra, often complicated with false passages and presenting great difficulties for instrumentation, he had never failed to relieve his patients through the operation he had outlined. He had never lost a patient, never had a serious hemorrhage or other dangerous consequence of the operation, or left behind a perineal fistula. These accidents were, therefore, separable from the well organized and skilfully executed operation and could not constitute any basis for a valid argument against it. Dr. Fluhrer instanced a few typical cases showing the results of the operation in which the caliber of the urethra had not only been promptly but permanently restored, and the patient spared the long-continued after treatment with dilating instruments. The operation had been made one of precision through the refinement of its component elements and through the instruments shown, whose action afforded an extended range to the niceties of the touch. Considering the brilliant results of the operation in its application to tight strictures of the deep urethra, Dr. Fluhrer was convinced that it was not only the treatment of preference for these strictures but was strongly of the opinion that the same beneficence of results could be extended to strictures of moderate or even large caliber, especially in the deep urethra.

Dr. MARTIN W. WARE inquired by what physical means prior to the introduction of the finger at the operation, could the presence of a stenosis of the vesical neck be proven.

Dr. FREDERICK BIERHOFF said that there was one particular point that had not been mentioned in the discussion on strictures of the urethra, and that this was the preventive treatment. It was generally admitted that a very large proportion of these cases were due to gonorrhea and the treatment of gonorrheal inflammations was, therefore, a very important part in the treatment of strictures. Another point he called attention to was about instrumentation, and he stated that it had been his experience that in every case in which a patient could pass his urine, even though it be in droplets only, he could get a filiform into the bladder and then proceed to dilate the strictured portion and thus avoid operation, either external or internal urethrotomy.

Dr. CHARLES H. CHETWOOD said that many years ago, under the inspiration of his preceptor, Dr. Edward L. Keyes, Sr., he was taught that there existed a form of obstruction in the posterior urethra at the neck of the bladder, not essentially prostatic obstruction, which caused complete retention of urine and was due to inflammatory conditions anterior to or behind the neck of the bladder, of intense character or of long duration; it was, in fact, a fibrosis surrounding the bladder orifice. To distinguish this condition of stricture of the neck of the bladder or fibrosis, Dr. Keyes had assembled the various names that had been given to it under the one of "contracture of the

neck of the bladder." It was best recognized during operation by the finger introduced through the membranous portion of the urethra, through the prostatic portion to the neck of the bladder, where it could be readily felt as the finger could not be passed through it without the employment of some force, which was not the case with the normal orifice of the bladder, which the finger would pass through without resistance. What Dr. Chetwood wished especially to emphasize was that this stricture, or contracture of the neck of the bladder, fibrotic in character, did exist, and that it was a distinct type; it occurred both alone and associated with prostatic enlargement, when it might account for the symptoms, and when a cure could not be expected without appreciation of its important bearing.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held February 24, 1910.

DR. S. M. BRICKNER IN THE CHAIR.

Report of a Case of Erythema Multiforme Gestationis (Fourth Attack).—Dr. WILLIAM S. GOTTHEIL reported the case of a patient, otherwise entirely healthy, who had been four times pregnant since her marriage in 1900. Each time when her pregnancy had been a few weeks old she had had a severe attack of erythema multiforme, the lesions in the early part of the outbreaks being papular and erythematous, later of the iris form and vesicular, and finally bullous. This eruption persisted during the entire pregnancies, and continued for from four to eight weeks post partum. Three of the attacks had been observed by him personally. Save in so far as it alleviated the pruritus and protected the denuded surfaces, the treatment employed had not been of much effect. On the other hand, the termination of the pregnancy and of the post partum metabolic processes, appeared in each instance to have caused a cessation of the outbreak. Dr. Gottheil said he preferred to make the diagnosis of erythema multiforme rather than that of dermatitis herpetiformis on account of the very characteristic appearance of the eruption in the three outbreaks that he had observed.

DR. SAMUEL M. BRICKNER said that skin lesions occurring during pregnancy had interested him very much and he had been fortunate enough to see different kinds of eruptions occurring at this period, but he had never seen an instance of erythema multiforme gestationis. The only very serious case he had ever seen appeared at the Mt. Sinai Hospital some years ago. About four years ago he had first described a peculiar condition of the skin arising during pregnancy that from its pathological picture simulated fibroma molluscum and hence was named fibroma molluscum gravidarum (*American Journal of Obstetrics*, February, 1906). This consisted in peculiar whitish, or brown, sometimes black wart-like excrescences upon the neck and under the breasts, appearing during the early months of pregnancy and becoming darker as pregnancy advanced, and then disappearing toward the end of gestation or six or eight months later. In every instance of this nature that he had seen, these excrescences entirely disappeared after the pregnant state. Halban of Vienna about the same time described a condition that probably had been seen before, an appearance of lanugo-like areas only occurring during pregnancy. They probably were not very rare. Only last summer Dr. Brickner had seen a patient with an intense eczema which appeared during the last month of her pregnancy and disappeared promptly after the birth of the child.

DR. WILLIAM S. GOTTHEIL said that although he had seen many cases of erythema multiforme he had never before had occasion to consider them in connection with pregnancy.

Large Retroperitoneal Tumor Probably Arising from the Transverse Colon Between the Layers of the Transverse Mesocolon.—Dr. HERMANN GRAD reported this case. The woman applied at the hospital for the removal of a tumor which had been discovered during a physical examination for a position before the Civil Service Board six months before. She presented on admission an abdominal tumor, filling the entire cavity, but the bulk of the mass was situated in the upper abdomen. It was hard and unyielding. The pelvic examination showed it to be free of the tumor. A diagnosis of tumor of the upper abdomen of doubtful nature was made, although it was believed that it was of pancreatic origin. When the abdomen was opened the tumor was found to be postperitoneal, adherent to the transverse colon, and filling the entire upper abdomen. In the attempt at enucleation the tumor ruptured, causing a severe blinding hemorrhage. The enucleation was rapidly completed and then it was found that there was a rent in the transverse colon about an inch in diameter; this was immediately repaired. The transverse colon was dropped back into place, the torn peritoneal surfaces were repaired, and the abdomen closed without drainage. The patient left the bed in two weeks. The abdomen was now flat and the incision appeared normal. The nearest diagnosis the pathologist could make was a fibrosarcoma arising from the transverse colon and invading the transverse mesocolon. The clinical symptoms were not indicative of malignancy and, therefore, a definite diagnosis could not be arrived at.

DR. ROBERT T. FRANK reported an instance in which a tumor appeared in the same situation as did the one reported; it was retroperitoneal and was situated between the stomach and the transverse colon. He excised a portion of the tumor, submitted it to the pathologist, and the report was that it was a fibrosarcoma probably of pancreatic origin.

Repair of Central Laceration of Levator Ani and Perineum.—Dr. JAMES N. WEST presented this, the paper of the evening. He said that the repair of a lacerated perineum was an operation of such minor character that its real importance was by no means appreciated even by those who performed the operation the most frequently. When the pathological conditions which might follow a laceration through the levator ani and the destruction of the support given by this muscle, "the diaphragm of the pelvis," were considered one must realized its importance. The unfortunate woman who had had the support of the pelvic contents destroyed felt as though the pelvic contents were coming out of the body with every effort at lifting or the performance of any act in which the muscles of the abdomen played an important part. Even the act of defecation tended to draw the uterus downward and backward and to force the rectum forward though the hiatus created by the laceration. This force continuing to act by degrees led to retroversion of the uterus and to pushing forward of the rectum into a rectocele, to descent of the anterior vaginal wall and the formation of a cystocele and often eventually to a prolapse or procidentia uteri. All these evils with their associated pathological conditions followed naturally as a result of the descent of the pelvic organs. In a recent work on gynecology it was stated that thirty-three different operations had been described for the repair of a lacerated perineum. Did this mean that repair was so easy that it could be done satisfactorily in thirty-three different ways, or that operations usually performed had been so unsatisfactory that in the effort to reach out for a better operation thirty-three different methods had been devised? Dr. West believed the latter proposition was true. In his efforts to repair this injury he had tried to divest his mind of the thought of any particular man's operation and to make a study of each individual case, because each one had to be

operated upon according to the injuries found. In order to understand the exact nature of the operation to be performed one must thoroughly understand the anatomy of the structures to be operated upon and must recognize the change in the relation of the anus to the fixed parts, namely, to the pubis and the meatus urinarius. The usual measurement in the average woman from the meatus urinarius to the anus was from one and three-quarters to two inches; where the levator had been lacerated this measurement was about three inches. The operation should practically restore the normal distance. He was led to adopt the technique which he described by a study of the situation and action of the levator ani in normal vaginae. He found that it lay about three-quarters of an inch within the orifice of the vagina and that a certain portion of it seemed to pass down and incorporate itself within the vaginal wall, giving a sphincter-like action which held the posterior vaginal wall in contact with the anterior. He found that in the vast majority of cases the central decussating fibers of the levator ani had been torn apart. Often no scar was evident but the fasciculus of the muscle could be followed along the side of the vagina and the rectum could be seen to force itself between these bands. Dr. West said that the operation had been a little difficult until experience had taught him how to pick up this fasciculus of the muscle and the fascia with the suture from the sense of touch and also that it could be easily done by the sense of sight. For the upper landmark he took a point in the center of the vagina where the anterior and posterior walls came into contact, usually about two and one-quarter inches from the fourchette. At this point a suture of No. 3 catgut double was passed through the mucous membrane so as to get a firm hold upon it, to act as a landmark and for purposes of traction. The lower landmarks were the two lowest carunculae myrtiformes on each side. Beginning at the left caruncle myrtiformis a strip of mucous membrane was cut up to the upper landmark in the vagina. a corresponding strip was cut down to the right caruncle myritiformis. This process was continued until a complete denudation had been made down to the fourchette. This part of the operation was practically the same as practiced by Hegar. The second step in the operation and perhaps the most important one was picking up the levator ani muscle. The muscle was picked up first on the left side close to the side of the rectum and at the lowest point at which it could be felt. The suture passed from above downward on the left side and out toward the side of the pelvis gathering up distinctly the muscle near and at the side of the rectum; it then crossed over and passed from below upward on the right side gathering in the corresponding bundle of muscle and fascia. This suture was then tied so as to bring the fasciculis of the levator ani in front of the posterior vaginal wall. Two continuous sutures were taken with the same suture to bring together the little fold of tissue which had been formed by tying the first suture. These sutures remained buried. The best suture for this purpose was No. 1, forty or twenty day chromicized catgut. tied with three knots so that the ends could be cut short. He next made a similar row of sutures a little higher in the levator ani muscle thus bringing together a little broader band of muscles in front of the vaginal wall and incorporating it with the firm band of levator ani muscles and fascia. He next brought together the mucous membrane from the apex of the denudation downward. He then began at the apex of the triangle and brought together the denuded surface of mucous membrane until he came to the bridge of tissue formed by the united levator ani muscle with interrupted sutures of No. 2 chromacized gut. These sutures were passed down to the bottom of the sulcus formed by traction upon the carrying thread and lay about one-third of an inch apart. At this point the sutures no longer went to the bottom of the sulcus but passed in deeply enough to bring together the mucous membrane and a little of the cellular tissue beneath it. The object of these shallower sutures was to build up a symmetrical vaginal wall. The last of these sutures lay about one-third of an inch within the vagina from the carunculae myrtiformes. The next suture, which completed the union of the vaginal mucous membrane, was passed in opposite the top of the denudation under the caruncule myrtiformes and came out just beneath the last catgut suture. This suture, together with the other that completed the union of the perineum, was of silver wire. It was usually necessary to use from four to five of these sutures. They passed in radiating toward a common center which was deep within the denuded area and corresponded with the portion of the levator ani which had last been brought together with the buried sutures. These sutures passed deeply into the tissues and gathered up a substantial body of the elastic tissues of the perineum proper. The ends of the wires were drawn taut and twisted at right angles, each having a perforated shot placed upon it. The results in these cases had been extremely satisfactory, there having been no cases of breakdown of the perineum and examination afterwards showed that the anterior and posterior walls of the vagina lay in accurate contact and that the sphincter-like action of the levator ani was completely restored. In several cases in which he had had the opportunity to see subsequent labor there was no serious tear of the perineum; the perineum seemed to bear the strain of labor extremely well. It did not follow that in subsequent labors the levator ani would be torn. Dr. West thought that in this operation he had one of the most valuable procedures in the whole scope of gynecology.

Dr. Chas. Jewett said that the thirty-three operations to which Dr. West had alluded should not be taken as indicating confusion in the surgery of the pelvic floor but rather as the different steps in the process of evolution by which they had reached the technique employed by most operators. The aim of the modern operation, of which Dr. West's was a type, was to restore the levator ani muscles to something like their normal relation to each other. His notion of the injury and its repair would best be understood by a word concerning the anatomy of the levator. The principal muscles concerned were the pubococcygei, which swept from the posterior face of the pubic bone on either side and passed backward, laterally to the vagina and rectum, and went to the coccyx. This might be compared with the recti abdominis; just as in the latter the space between them, except where perforated for the transmission of the tubular viscera, was bridged by fascia. This fascial bridge might be looked upon as a conjoined tendon entirely similar to that between the recti. The essential character of most perineal lacerations was a rent in this conjoined tendon at one or both sides of the vagina. The rent resulted in diastasis of the levators and consequent displacement of the pelvic floor and viscera. The modern reparative technique was an attempt to correct the diastasis. Dr. Jewett's method of procedure was somewhat similar to that of Dr. West.

Dr. Samuel W. Bandler presented drawings to show his method of procedure in these cases for repair of lacerated perinei which supported Dr. West's statement as to the value of bringing together by sutures the torn levator ani-muscle fibers in a bridge-like form. The various steps that Dr. West followed constituted one of the best of the thirty-three operations in vogue. Dr. Bandler said he had seen Dr. Waldo do a single stitch colpoperineorrhapy and he had tried it and found that he got very good results and with almost no failures due to infection; he attributed this to the fact that in the operation there was not a buried suture or knot anywhere in the denuded parts that were brought together. He used a similar method in cases

of descent of the uterus, and even in cases of total prolapse. In those cases, however, he found subsequently a separation of the two halves of the denuded area that he had so well brought together, and instead of a linear scar from the posterior wall of the vagina to the anterior wall of the anus he found a scar that had resulted from a separation or a broadening, usually three-quarters of an inch wide, which gave little support to the rectocele. He, therefore, decided to bring together the two sides of the separated levator ani muscles by means of one, two, or three special buried sutures. He demonstrated how this was done by drawings. The method described by him was especially valuable in cases where there was a total prolapse of the uterus and in which the operation of perineorrhaphy was brought to the greatest test. The results of the operation he described were very satisfactory and infection was avoided.

Dr. Arnold Sturmdorf said that the title of Dr. West's paper was well chosen inasmuch as it directed attention to the evolutional factor in perineorrhaphy, namely, the repair of the lacerated levator ani muscle. This subject was elaborated by Dr. Sturmdorf and presented before the Medical Association of the Greater City of New York February 15, 1905, and published in the Medical Record April 1, 1905, although Dr. Holden, who wrote upon the same subject six months later in the *American Journal of Obstetrics* (October, 1905), was given all the credit by Dr. Kelly in his "Operative Gynecology," Second Edition. He said that obstructive retention could not replace normal visceral support, and the immediate aim in perineorrhaphy should be based on the elementary principle of accurate restitution of original anatomic relations thus restoring, as far as possible, functional as well as mechanical support to the pelvic contents. The keynote in the clinical significance and therapeutic indications of pelvic floor laceration was prolapse. Dr. Sturmdorf then quoted quite freely from his published article in the Medical Record.

Dr. Harry Aranow, in speaking in regard to Dr. Bandler's statement about Dr. Waldo's famous operation, colpoperineorrhaphy, said that Dr. Waldo only used these sutures in the milder cases; but in the severer cases he used a modification of the Hegar operation, an operation similar to the one described by Dr. West, differing only in minor details. Dr. Aranow believed that the method described by Dr. West was the only radical one for the repair of a lacerated perinum.

Dr. William H. W. Knipe said that in 1902 he had spent much time in dissecting out the levator ani muscle in both males and females, and after that he had had no respect for the perineal body, but all respect for the levator ani muscle. With regard to the question of priority of this operation as described by Dr. West, this method was employed with but a few different details by Dr. George M. Tuttle from 1903 to 1905; he used it in one hundred or more cases, and Dr. Knipe said he only knew of one case where he failed to obtain the desired result. Dr. Knipe said he had never used personally any other method. In most of the cases, after the levator ani muscle had been thoroughly sutured together with interrupted chromic acid catgut, little else was necessary to form a firm perineal body. He did not know why Dr. West had found it necessary to use silver wire sutures in these cases after the levator ani had been sutured; in all the cases he had seen and operated on, after the levator ani had been sewn up, he could see no reason for suturing the perineal body except for the cosmetic effect, using a continuous small catgut suture for this purpose.

Dr. Leroy Broun believed that all gynecologists appreciated the importance of the levator ani muscle as a support of the pelvic floor and when torn all aimed at coapting the lacerated parts, but with different techniques. The main thing was to bring up the posterior wall to lay against the anterior wall, and Dr. Broun's custom had been to do what was practically an Emmett operation, except in those instances where there was a large rectocele. His object in introducing the sutures was to take up a good bite on each side in order to go well behind the main edges of the muscle and fascia. It was a very difficult thing to make out the fibers of this muscle, the levator ani, or to be sure that the edges of the fascia could be seen with the eye. The only way he could tell that he had gotten together the edges of the muscle and fascia was by keeping the finger in the rectum; then one could recognize the body by the sense of touch. Even experts at this sort of work stated that they could not make out this muscle plainly, and some of them should give some reassurance to those who fail in this that the fault was not theirs. Dr. Broun frankly acknowledged that he found it difficult to point out the fibers of the levator ani muscle.

Dr. West, closing the discussion, thought that Dr. Broun's ideas regarding repair of lacerated perinei were the old ones and contrary to those which he had attempted to present in his paper. Dr. Jewett, Dr. Bandler, and all the other gentlemen who have spoken, agree with the author in the necessity of special sutures in the levator ani. Dr. West had found many cases that had been operated upon by various methods and without permanent results; these women returned, being miserable, weakened, and as discouraged as before the attempt at repair had been made. What he presented was a simple method of denudation, of picking up the torn or lacerated levator ani muscle, of bringing the fibers together, and closing the outer parts. The superficial sutures were introduced in order to restore the parts to their normal relationship. The priority of the operation he said he did not care to discuss.

MEDICAL SOCIETY OF THE MISSOURI VALLEY.

Twenty-second Semi-Annual Meeting, Held at Omaha, Nebraska, March 17 and 18, 1910.

The President, Dr. A. B. Somers of Omaha, in the Chair.

Psychotherapy in Relation to the General Practice of Medicine and Surgery.—Dr. Henry S. Munro of Omaha discussed psychotherapy in the field of preventive medicine; in the domain of psychophysiological therapeutics, as an adjunct in the treatment of acute diseases, as an aid to surgery in the treatment of chronic diseases, and in relation to the prevalent professional psychasthenia.

Dr. C. R. Woodson of St. Joseph, Mo., said that the physician who possessed the power to entertain, to divert, to inspire confidence, who could honestly set forth facts and take an individual's mind off of an object of worry, or who could influence him along these lines, was the best psychotherapist.

Dr. A. S. Von Mansfelde of Ashland, Neb., did not believe that a man could be educated to become a successful psychotherapist. The successful psychotherapist was born, not made. He cited instances to substantiate his statement.

Dr. R. Willman of St. Joseph, Mo., stated that instruction and investigation, if properly given and carried out, would do a great deal towards mitigating and annihilating pseudo-mind-healing. Psychotherapy was not new, but physicians had not practised it to the extent they should have done.

Dr. S. Grover Burnett of Kansas City, Mo., stated that before attempting to administer psychotherapy, the physician ought to make a diagnosis. Without a diagnosis, he had better not say or do anything. If a physician had not diagnosed correctly the ailment of a patient, he was just as likely to give pathological suggestions as he was to give physiological ones. Babinski said that functional conditions, such as so-called hysteria, were caused by sugges-

tion and relieved by persuasion. While all members of the profession were not ready to accept that, the more one studied it, the more clearly he saw the basis of such a statement.

Dr. O. Beverly Campbell of St. Joseph, Mo., said he did not believe that 75 per cent. of the people were neurasthenics. He had observed this, that as he was becoming a better diagnostician from day to day, he was able to find pathological conditions as causes in more cases of neurasthenia than he ever did before. He believed confirmed neurasthenics needed suggestion. They needed to be told some things they did not know. If they were in fear of a great calamity, if they believed they were in a serious condition, and the physician could diagnose their cases correctly and say to them, you are not in a serious condition, then psychotherapy was of advantage.

Dr. F. B. Dorsey of Keokuk, Ia., said there was not a practitioner of medicine to-day who was not using psychotherapy to a greater or less degree, but there was a limitation to it. A short time ago he had a case of confirmed neurasthenia. A diagnosis of gall-bladder trouble was made, and the operation disclosed a gall-bladder full of stones. After these were removed the neurasthenia disappeared.

Dr. C. C. Goddard of Leavenworth, Kan., said the general practitioner chased dollars too hard to make accurate diagnoses. He found that when cases of neurasthenia were admitted into private institutions they had not been properly examined by the family physician. If they had been the patients never would have been sent to such institutions, but treated at home. He thought pathological conditions were at the bottom of the majority of cases of neurasthenia.

Dr. W. O. Henry of Omaha said the value of this paper lay in the fact that the author emphasized the point that all physicians should employ psychotherapy. They should cultivate it as a means of diagnosis, but not to the exclusion of other things. Psychotherapy should be taught in the medical schools. He believed more attention would be given to it in the future than there had been in the past.

The Errors of Mind Healing.—Dr. R. Willman of St. Joseph, Mo., referred to the various cults, and said they were a danger to the human family. He summed up the dangers that followed in the trail of the pernicious practices of the healing cults, as follows: 1. The mind-healer being a non-believer in the existence of disease, its contagion, infection, etc., did not appreciate the necessity of knowing disease, and because of his unmindfulness of the danger of contaminating others, he left all gates open to the spread of disease. 2. The mind-healer had no idea of early diagnosis and proper treatment of disease when it was in its incipiency. Thus the patient was deprived of all opportunity to protect himself from danger and loss of life—things which early diagnosis and proper treatment could easily prevent.

Hemiplegia.—Dr. F. E. Coulter of Omaha read a paper in which he reported a case with acute onset, and exhibited the patient. From the history, distribution and character of the paralysis, the alteration of the reflexes, the Babinski phenomenon, spasticity, etc., the case obviously belonged in this category. He called attention to the salient points of practical importance in the management of such cases.

Dr. R. C. Woodson said the mode of onset of lesions of the central nervous system was of more importance to the physician in making a diagnosis than anything else.

The Nonsurgical Treatment of Tuberculosis Arthritis.—Dr. H. Winnett Orr of Lincoln said that many patients who had old tuberculous sinuses would have recovered without operation in from six months to a year if carefully treated mechanically. Operative interference, even under the best conditions, prepared the way for mixed infection later. He discussed the merits of different forms of mechanical treatment, as traction in bed, traction splints, braces, and plaster-of-Paris.

The Neglect of the Sacroiliac Joint by the General Practitioner.—Dr. Edward Evans of La Crosse, Wis., emphasized the anatomical importance of the sacroiliac joint, saying its neglect in the diagnosis of painful and disabling conditions about the back and pelvis led to improper treatment. He cited illustrative cases. He described the symptoms of strain of this joint, and then discussed the diagnosis and treatment.

Dr. A. S. Von Mansfelde said men in throwing sacks of grain over their shoulders sometimes produced a partial dislocation of the sacroiliac joint, which continued for years and was referred to as chronic Bright's disease, lumbago, chronic rheumatism, etc., when in reality it was nothing more than the dislocation of this joint, complete or partial, which was the cause of the trouble.

Dr. Winnett Orr had seen two cases in which the sacroiliac joint had been strained in the manner described by the essayist.

Dr. S. Grover Burnett related a case of a lawyer who sustained an injury in leaping from a street car. The hip-joint seemed normal, but when any force was brought to bear upon the pelvis pain was intense along the sacroiliac joint.

Dr. F. B. Dorsey narrated a case of a pregnant woman who sustained a complete disarticulation at the symphysis and the right sacroiliac synchondrosis. Treatment consisted in placing her in the dorsal position and applying a plaster cast from a little above the waist-line down to and below the knee, immobilizing the knee and the hip. She made a perfect recovery and pregnancy was uninterrupted.

Dr. Mary Strong of Omaha asked whether the Walcher position, which was frequently used in cases of slight degree of contraction of the pelvic inlet, was likely to injure the sacroiliac joint.

Dr. Evans said that if we put a patient in the Walcher position and applied high forceps and strained the sacroiliac joint severely, naturally we took care of it afterwards; but these slight strains were not cared for by practitioners.

Certain Facts in Ophthalmology of Practical Importance to the General Practitioner.—Dr. John Monroe Banister of Omaha said it would be most advantageous to the busy medical practitioner in general practice to possess sufficient ophthalmological knowledge to recognize the ocular conditions demanding immediate attention, and to acquire the small amount of skill necessary to palliate such urgent affections until the services of a specialist could be secured.

The Use of Antitetanic Serum in the Treatment of Tetanus.—Dr. F. B. Dorsey of Keokuk, Ia., emphasized the necessity of giving repeated doses of this serum at stated intervals as a prophylactic. Large and repeated doses did not counteract tetanus when once established.

Dr. C. C. Goddard said that antitetanic serum must be used early or not at all. There was one remedy he was going to try and use it to the limit, and that was apomorphine, as he believed one would get more benefit from it than from chloral.

Dr. R. William mentioned a case of tetanus in which he used apomorphine, as well as sulphate of magnesia and sulphate of soda combined, with gratifying results.

Dr. O. Beverly Campbell said sulphate of magnesium and sulphate of sodium were good in their place, but when tetanus was fully developed he would just as soon use Missouri River water. He had never seen a case of true tetanus cured by any method of treatment.

Should the Operation for Ruptured Tubal Pregnancy Be Immediate or Deferred?—Dr. John E. Summers of Omaha stated that in the majority, say about 95 per cent.

of cases of ruptured tubal pregnancy, no operation should be done until reaction from the shock of rupture had taken place. In the remaining 5 per cent. of these cases no delay was admissible. The urgency for operation could be recognized in most patients by the difference in the initial symptoms. In borderline cases the same rules of recognition applied.

Dr. B. B. Davis of Omaha said he had done many of these operations, and many of these patients would go through the original hemorrhage and shock and would rally and be in a much better condition for operation than at the beginning of the hemorrhage. For a long time he took the position that cases of ruptured tubal pregnancy ought to be operated on at once, but for the last two or three years he had delayed operation for at least a few hours.

Dr. O. Beverly Campbell said he believed every case of ruptured ectopic gestation was a law unto itself, and the judgment of the surgeon should be used. In many of these cases delay in operating was indicated. His experience had been that in most cases a blood clot would form and hemorrhage ceased, and that they should wait until shock had passed off and the patient had reacted before operating.

Dr. Donald Macrae of Council Bluffs, Ia., said he was not in a position to differentiate between one case and another, and to say that this case was or was not in a serious condition, and so in cases of ruptured tubal pregnancy he was going to operate as soon as he could, as he did not know which case was going to terminate fatally.

The Physical Basis of Mental Disease.—Dr. Frank P. Norbury of Hospital, Ill., delivered the oration in medicine, and, among other things, said that the interrelationship of mind and body would ever be a fruitful field for discussion, and might never be solved to the satisfaction of all, but the time was coming, and not far distant when the somatic would have precedence over purely mental symptoms. Therapeutics must and would be adjusted to meet the conditions as they were, not as they were supposed to be.

Local Anesthesia.—Dr. Leonard Freeman of Denver delivered the oration in surgery. He referred to the early history of chloroform and ether and the dangers attending the administration of these anesthetics. Nervous and hysterical patients were not suitable for local anesthesia. The patients must be selected with care and the surgeon must consider age, temperament, nervous control of the individual, etc. Among the operations which could be done under local anesthesia he mentioned the removal of tumors of the scrotum, castrations, epididymectomies, varicocele, and hydrocele operations, etc.

The Rapid and Complete Cure of Gonorrhea.—Dr. Thomas M. Paul of St. Joseph, Mo., said a cure was not complete unless it resulted in the absolute eradication of gonococci from the genitourinary tract, and such a cure could never be rapid in the sense in which that term was used by the laity.

Why the Indifference of the Profession to Morphinism Should Be Changed.—Dr. S. Grover Burnett of Kansas City, Mo., described three types. 1. Simple morphinists belonged to the better class of mentalities. They inherited or acquired a tendency to nerve weakness by exhaustive taxations of nerve energy. The drug was taken to relieve physical and exhaustive nerve discomfort. 2. Morphinomaniacs were lower in intellectual stability and acquirements. They inherited weakness or nerve and mind energy was the rule and a predisposition to add acquired exhaustive statis was strong. The drug was taken to relieve exhaustive psychic pain, mind pain, mind discomforts. The action of the drug was to cause further mind deterioration in a mind already near the borderline of insanity. 3. Delusional or motiveless morphinists were sufficiently over the borderline of insanity to cause them to take the drug because of faulty mind, delusional states. It was apt to end in a terminal insanity.

Treatment of Localized Appendicular Abscess.—Dr. Van Buren Knott of Sioux City, Ia., said the removal of the appendix at a secondary operation was frequently very difficult because of the density of the surrounding adhesions and in the majority of instances it would be found much easier to remove it at the first operation, and this should now be done rather than subject the patient to a prolonged and often serious operation. The incision was invariably made through the right rectus muscle, splitting the fibers and the peritoneal cavity freely opened. A small gauze pack was tucked into the upper angle of the wound and so adjusted as to prevent any extravasation of pus towards the liver or diaphragm. Another small pack was tucked in towards the median line from the upper angle of the wound to the lower pelvis to prevent any extravasation towards the left. The abscess cavity was then freely opened with the fingers, unless opened by the peritoneal incision, and the pus rapidly mopped up with gauze sponges. The appendix was then exposed and removed. All adhesions separating the abscess cavity from the lower pelvis were now freely separated and the pus or sero-pus, which was usually found in the lower peritoneal pouch, was rapidly mopped up with sponges. A large split rubber tube, from one-half inch to one inch in diameter and carrying a wick of iodoform gauze was inserted through the lower angle of the wound to the bottom of the rectovesical pouch, or cul-de-sac, the protecting gauze removed and the wound closed down to the tube with interrupted through-and-through silkworm sutures. Attention was called to the large size of the tube, as he believed the first two hours of drainage were those which counted. This method was not advocated for the occasional operator, but for men of great experience.

Increasing Mortality in the United States from Heart, Brain, and Kidney Lesions.—Dr. W. F. Milroy of Omaha directed attention to the enormous increase of deaths from these diseases and offered suggestions as to what may be done by way of remedies.

The Treatment of Angiomata and Nevi.—Dr. John Prentiss Lord of Omaha said that the angiomata fell within the pale of surgery, while nevi, involving the skin only, fell within the sphere of dermatology. The conditions were so frequently associated that it became impossible to divide their treatment. He spoke of the superior value of boiling water in the treatmtent of angiomata and of carbon dioxide snow in treatment of pigmented hairy nevi.

THE PRACTITIONERS' SOCIETY OF NEW YORK

229th Meeting, Held February 4, 1910.

Dr. John W. Brannan, President, in the Chair.

A Child Operated on for Very Bad Tuberculous Peritonitis Remaining Cured for Twelve Years After.—Dr. Abbe reported this case on account of the remarkable recovery of the patient, who was a child two years old at the time of the operation. The only physical findings at the time of operation were the great pallor, ascites, and daily fever. Laparotomy revealed a tuberculous peritonitis of the most extensive nature. The peritoneum was one-quarter of an inch thick in many places and there were large masses of thick turbercle and caseating nodules. In the pelvis the tuberculous masses could be scooped out in large pieces. These masses were cleared away, the peritoneal cavity was washed out, and peritoneum smeared with camphor naphthol (method of Rendu). The patient made a good recovery and at present shows no signs of tuberculosis. The abdomen was symmetrical, soft, and not distended. There had been no ascites or obstructive symptoms since the operation. At the time of operation about one gallon of

fluid was obtained and the temperature had been 101.5° to 102° F. for some time.

A Young Woman in Perfect Health Eighteen Years After Removal of a Very Large Renal Sarcoma.—Dr. Robert Abbe showed this patient on account of the absence of recurrence for a longer period than any recorded in surgical annals. At the time of operation she was one year and two months old and weighed 22½ pounds. The mother had noticed a slight enlargement of the abdomen only six weeks before and since that time the child had lost in weight and strength. The case seemed quite hopeless on account of the rapid development and large size of the tumor, as well as the poor condition of the child. She was operated on in November, 1892; the Trendelenburg position was employed and the limbs were swathed in cotton. After making a small exploratory incision, a long transverse cut was made from the median incision to within two inches of the spine. A huge, vascular tumor was found which was removed with difficulty on account of the great vascularity. The tumor occupied the upper pole of the kidney and examination showed that it was possible to amputate the kidney above its pelvis, leaving an inch and a half of apparently sound structure attached to the tumor. This was done after ligation of those vessels passing to the tumor mass. The recovery was uneventful and the patient had never been ill since the operation. The case was very unique in that the patient had remained well for such a long period and there was no reason why the recovery should not now be regarded as permanent. The patient had a perfect scar without a sign of hernia. Pathological examination of the tumor showed a mixed growth,

Fig. 1.—Sarcoma of the kidney in a nursing child of 14 months, weighing 15 pounds after the operation.

Fig. 2.—Same child as in Fig. 1, in perfect health, more than a year after the operation.

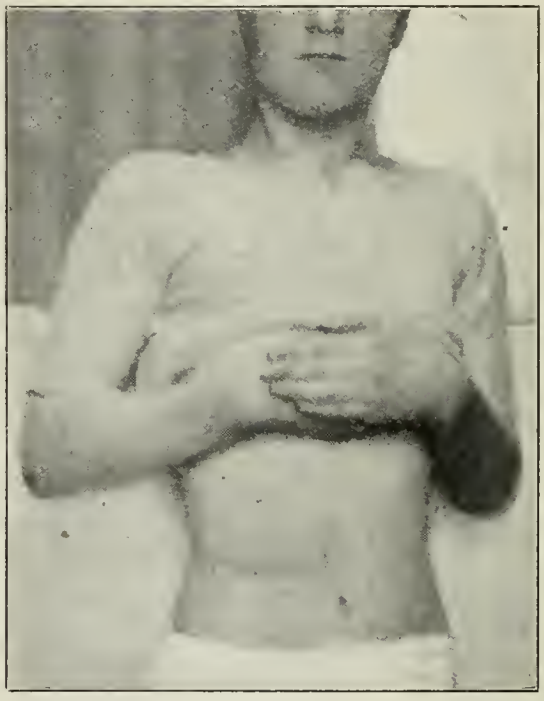

Fig. 3.—Same patient as shown in Fig. 1, eighteen years after the operation.

rhabdomyosarcoma, containing a large proportion of round and spindle-celled sarcoma with some striated muscle structure.

Visceral Sarcomata; Cases of Sarcoma of the Stomach, Heart, Mediastinum, Etc.—Dr. W. Gilman Thompson read this paper (see page 563).

Dr. Abbe spoke of the interesting frequency of internal sarcomatous metastases from pigmented moles. Primary internal sarcomata were not found as frequently, with the possible exception of ovarian sarcoma. The latter were very amenable to operative treatment. Pigmented moles could be removed very safely by the knife, if widely circumscribed, especially if skin was grafted after the operation. He had seen several cases, however, followed by a rapid general sarcomatosis, where the growth had been carelessly removed. Removal of the mole by excision after irritation involved some risk. Radium removed pigmented moles neatly and with least scarring. In cases where there was much irritation radium retrograded the superficial tumor, but did not affect the disseminated metastases. He did not advocate the use of knife or radium in cases where there was active irritation of the mole.

Dr. Blake spoke of a case of pigmented mole, in a young woman, which was situated at the umbilicus. This was excised and in about one year the patient had acute abdominal symptoms similar to those of peritonitis. There was vomiting, but no fever; later, there were evident signs of peritonitis and intestinal obstruction. The patient was operated upon and a melanotic bleeding growth was found in one ovary. There were also minute pigmented spots in a fibroma in the uterus. A microscopical examination of the ovarian growth and the pigmented areas from the fibroid of the uterus revealed a structure identical with that of the mole removed the year before; namely, a pigmented epithelial neoplasm, or, in other words, a pigmented carcinoma.

Successful Operation for Removal of Cerebellar Tumor.—Dr. M. Allen Starr reported a case of cerebellar tumor, which was first seen by him in October, 1908. The patient at that time showed a slight weakening of the external rectus on the left side, with defective winking. This was the only symptom, but later the patient developed headache, vomiting, slight choked disk, and considerable vertigo. No history of lues was obtained, but in order to rule out that as a possibility the patient was put on specific treatment. This had a marked effect for two months, but then symptoms returned and increased and became quite severe. He developed a cerebellar stagger with a tendency to fall to the right. The paralysis of the left side of the face increased and deafness of the left ear ensued with tinnitus aurium. There were also vagal attacks, characterized by faintness and slow pulse, due to irritation of the pneumogastric nerve. An operation was strongly advised, and the patient was sent to the Johns Hopkins Hospital in Baltimore. On May 20, 1909, an operation was performed by Dr. Cushing, the entire cerebellum being exposed in order to render the deeper parts accessible. When the dura was exposed the cerebellar tissue was found to press down into the foramen magnum. The posterior portion of the foramen was removed as Dr. Cushing considered such a step advisable in all cases of cerebellar tumors. Sudden death might occur in these cases from compression of the medulla and in this case a grooving of the cerebellum by the pressure of the bone was seen. A tumor was found in the region of the acoustic nerve and was removed without injury to the deeper parts. The patient made an uninterrupted recovery, and when last seen, in January of this year, was perfectly well. The only symptom that still persisted was a slight nystagmus on looking to the left. The optic neuritis and interlacing of the visual field had entirely disappeared. Examination of the tumor removed showed a small, hard, encapsulated fibroma. Tumors in this location have generally been fibromata of this nature. Dr. Starr said that there were 270 cases of operation for cerebellar tumor on record. In this series of operations 162 tumors had been removed and the patients were well three months after the operation. He spoke of the distortion of the color fields and thought it a very reliable symptom in cases of tumor. The question of its being due to the choked disk alone had arisen and some observers thought it an accompaniment of choked disk from any cause.

Pathological Society of Philadelphia.

At a stated meeting, held March 10, Dr. John Speese exhibited a specimen of "carcinoma of the larynx," obtained from a man with characteristic symptoms, and for the relief of which, after tracheotomy, laryngectomy had been performed. The case pursued a favorable course for a week, when acute edema of the lungs set in and terminated fatally. The growth was situated within the larynx and there had been no extension to adjacent parts. Dr. D. B. Pfeiffer presented a specimen of "rhabdomyoma of the kidney" from a child thirteen months old, in whom rapidly increasing abdominal swelling had been observed for three months. The case was not considered suitable for operation and it pursued a progressively unfavorable course until death ensued. After death an enormous growth was found largely filling the abdomen and displacing the contained structures. Histological examination disclosed the presence of fibrous tissue and striped muscular fibers in considerable amount. Dr. Pfeiffer presented also a specimen of "teratoma from the kidney region." This was obtained at operation on a child a little more than a year old. Its relations with the left kidney were so intimate that this organ also was removed. Histological examination showed the formation to be made up of many different kinds of structure, cartilage, bone, intestine, brain. The little patient survived. Drs. Charles S. Potts and Howard T. Karsner exhibited a specimen of "endothelioma of the brain." The patient had been a man with partial palsy in the extremities on the right side, occasional clonic movements in the affected parts, slight aphasia, hemianopsia, and little or no headache, and vomiting. Post-mortem examination disclosed an enormous tumor on the surface of the left hemisphere arising from the dura and creating a depression in the brain into which it fit snugly. Dr. Judson Daland presented a specimen of "bullet wound of the heart," obtained from the body of a colored man who had been shot from the left side, the missile entering the right ventricle at one point, passing through this cavity and making its exit from another point of its wall and finally entering the liver. The patient lived for about ten minutes after the shot had been fired. Dr. E. W. Holmes presented a communication entitled "Acid-fast Bacilli in Waters." He had made numerous examinations of waters, distilled, artesian, drawn from tap, and other sources, and had succeeded in finding acid-fast bacilli in varying number, particularly when the water had been standing for some time. The bacilli could not be found in freshly distilled water. It was believed that the organisms represented contamination from the air. Dr. Eugene L. Opie of New York presented a communication entitled "Experimental Cirrhosis of the Liver." He cited experiments to show that cirrhosis of the liver could be induced in animals by the administration of chloroform by inhalation or the stomach, if at the same time infection were induced, as with *Bacillus coli communis*, *Streptococcus pyogenes*, or the staphylococcus. The condition was one of recurrent degeneration of the parenchyma of the organ, with a tendency to recovery, provided the insult be not repeated.

Teething.—Shropshire says that in the case of a teething child, we have actually two patients—the child, who needs its alimentary canal cleaned out, and the mother or nurse, who needs a large dose of plain facts, emulsified with clear and terse directions for infant feeding—*Texas Journal of Medicine.*

Presence of Trypsin Ferment in the Stools of Healthy and Sick Babies.—G. Rovere experimented to ascertain whether trypsin was present in the intestines of infants whether sick or well. He tested for the trypsin in the feces of children from birth to eight and nine years of age. In new-born children who have not suckled the meconium shows no trace of trypsin, due to the lack of intestinal peristalsis, not to absence of production of trypsin in the intestine. As soon as suckling begins peristalsis is excited reflexly. In the first year of life the reaction for trypsin is very prompt. The function of the pancreas does not suffer by the occurrence of intestinal trouble. The author concludes that the trypsin ferment occurs in the feces of infants as early as the second or third day of life; in the most varied diseases the trypsin reaction is never absent.—*Rivista di Clinica Pediatrica.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of March 26, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	695	222
Diptheria	386	42
Measles	1,539	31
Scarlet Fever	716	49
Smallpox	—	—
Varicella	141	—
Typhoid Fever	35	7
Whooping Cough	35	3
Cerebrospinal Meningitis	8	7
Malarial Fever	—	—
Totals	3,555	361

Bacteria in the Eye of the New Born.—Rosenhauch, after examining the conjunctival sacs of two hundred new-born babies, came to the following conclusions: The conjunctival cul-de-sac is absolutely clear immediately after birth. The first microorganisms appear twenty-four hours after birth. After twenty-four hours the bacterial flora is constant. It is not to be differentiated from the adult. The *Staphylococcus non pyogenes, non liquefaciens,* and the *Bacillus xerosis* are constant inhabitants. Other microorganisms are only sporadic. Pathological microorganisms are seldom found, and then only a few. Twenty-four hours after birth the conjunctival sac was never free from microorganisms. Gonorrheal infection is hardly possible during birth, but usually occurs during the first couple of days of life.—McKee in *The Montreal Medical Journal.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended March 25, 1910:

		CASES.	DEATHS.

ERRORS OF DIAGNOSIS IN SURGICAL LESIONS OF THE KIDNEY.

By ALEXANDER B. JOHNSON, M.D.,

NEW YORK.

THAT errors of diagnosis in surgical lesions of the kidney are frequent will, I think, be admitted by all. The consequences to patients may be serious. Operations may be omitted which should be performed, or operations may be performed in cases where no necessity for such procedures exists, or an operation may be performed which does not fulfill the needs of the individual case.

I have thought it worth while to enumerate some of these diagnostic errors and to point out how and why they occur and how they may best be avoided. Many of these diagnostic errors have come within the range of my own experience, and have been made by myself, or by surgeons with whom I have been associated. I have chosen to group the cases according to the pathological lesion rather than to describe errors which may occur in the presence of certain signs and symptoms. The following grouping has been made:

1. Injuries of the Kidney. 2. Movable Kidney. 3. Hydronephrosis. 4. Suppurative Lesions of the Kidney. 5. Tuberculosis of the Kidney. 6. Stone in the Kidney. In a subsequent paper will be considered the error which may occur in other surgical lesions of the kidney.

1. *Injuries of the Kidney* may be divided into—a. Subcutaneous Wounds. b. Open Wounds. (a.) Subcutaneous Injuries.—While the diagnosis of severe subcutaneous injury of the kidney is as a rule, quite simple, nevertheless serious diagnostic errors are possible. The cardinal signs and symptoms of rupture of the kidney are: Following an injury to the loin the patient suffers from pain in the region of the kidney. There is tenderness over the kidney and the patient passes bloody urine per urethram. Shock may or may not be present.

The symptom hematuria or its absence may be misleading. It is to be borne in mind that after very serious injuries of the kidney, namely, those in which the ureter is torn across, or, in which that canal, being violently stretched or contused, has become clogged by a blood clot, the quantity of blood in the urine may be small, microscopic, or blood may even be absent. If the ureter is thus early plugged, the appearance of blood in the urine may be delayed for many hours; or even if the kidney be extensively pulpified, for a longer period. In this group of cases the occurrence of severe renal colic may aid in establishing the gravity of the injury.

In a certain grave form of subcutaneous injury hematuria may be intermittent. I refer to that group of cases in which a considerable artery is torn within the kidney without rupture of the capsula propria and with the formation in the substance of the organ of an arterial hematoma or traumatic aneurysm. In these cases, while a greater or less increase in the size of the organ may occur, such increase may not be discoverable upon palpation. The surgeon may be misled by the intermittent character of the bleeding into the belief that it has ceased permanently. The intermissions may be prolonged for days, or even weeks; and at the end of such times, bleeding may recur in such large amount as to produce a dangerous degree of anemia, or even to bleed the patient to death. Such an occurrence is well illustrated by the following case, which was observed in the service of Doctor Charles McBurney in the Roosevelt Hospital in 1894.

The patient was a boy, aged sixteen years. A week before coming to the hospital he had fallen, while running, against a wooden beam, injuring his right loin. He had not suffered from shock, and had walked a considerable distance to his home, where he went to bed, and remained during the following week. He had observed that his urine was red after the accident. Upon admission to the hospital his temperature was 99° F., his pulse 100. He was passing a diminished quantity of urine, 14 ounces in twenty-four hours. This was slightly brownish in color, and contained a moderate amount of blood. There was pain in the region of the right kidney, moderate tenderness, and muscular rigidity. He left the hospital against advice, at the end of three days, feeling better, and desired no further treatment. Twelve days later he returned. On the preceding day he had passed a large amount of blood *per urethram*. There was no tumor in the loin nor noticeable tenderness. At this time his pulse had become rapid, 110. He had a slight amount of fever. His urine contained some blood. Upon the two following days he passed a considerable quantity of blood with the urine. The bleeding continued during the next five days with the symptoms of progressive anemia. Three weeks after the accident his right kidney was removed. The kidney was slightly enlarged. There was a bulging tumor at the center of its convex border. Upon incising the kidney a considerable cavity was found in the kidney substance, an inch and a half in diameter. The cavity contained a globular clot of bright blood, inclosing firm clots and masses of fibrin, partly decolorized. In the wall of the cavity an open mouth of an artery of considerable size plugged with a soft and recent thrombus was discovered. The cavity communicated by a small orifice with one of the calyces. The capsule of the kidney was not ruptured. The patient did not survive.

The following case history illustrates that a serious subcutaneous rupture of the kidney may be

attended by trifling symptoms at first. In this case the kidney and pelvis of the ureter were torn by a fall against a hard object. The persistent hemorrhage would, no doubt, have caused the patient's death had not the kidney been removed.

A. C., male, aged fifty-nine years, native of France, a cook. On July 6th, 1907, at about 7 A. M. he was lowering a small cart down some stone steps. He stumbled and fell a distance of only two or three steps, striking on his left side against the edge of the lowest step. He experienced a sharp pain in his left side, but arose, went about his work, and did not consider himself seriously hurt. He had some pain like a stitch, in his left side, some difficulty in taking a long breath, and that was all. Nearly eight hours later he had a strong desire to urinate; he went to the closet, urination was difficult and painful, and he observed that his urine was deeply stained with blood. He sent for an ambulance and was brought to the New York Hospital.

On Admission.—The patient is a large stout, man. Skin and mucous membranes normal in appearance. There is a fracture of the tenth rib on the left side about three inches from its anterior extremity. Abdomen.—There is tenderness beneath the free border of the ribs in the left hypochondrium, and tenderness in the lumber region of the same side. Temperature, 98.2° F., pulse 76; respirations, 20. The patient urinated liquid of a dark wine color. He entered the service of Doctor F. W. Murray. He was kept quiet in bed. His urine continued bloody. On the eleventh day of July, four days after admission, his hemoglobin was 60 per cent., on the seventh day 58 per cent., on the ninth day after admission it was 52 per cent. On that day the kidney was exposed by Doctor Murray through a five-inch incision parallel to the twelfth rib. The fatty capsule of the kidney was found infiltrated with blood. The kidney itself appeared swollen in its lower half. The capsula propria was incised and the incision gave exit to blood clots. The hematoma was cleaned out and the wound in the capsule drained by a strand of gauze. Suture of the external wound. The patient then fell under my care. From July 15th until July 19th he continued to pass bloody urine. He suffered from pain and difficult urination and much vesical tenesmus. On this day I exposed the kidney through the same incision. A jagged rent was found in the posterior surface of the kidney near its lower pole. The tear extended from a point an inch and a half distant from the hilum inward and opened the pelvis of the ureter for the distance of an inch. The borders of the rent in the kidney substance were friable and appeared to be necrotic. The kidney was removed. The patient made a good and satisfactory convalescence. In addition to the lesions described, the kidney contained several small areas of contused tissue resembling infarcts. These were necrotic.

In the group of cases in which the capsule of the kidney is torn and the organ itself is extensively pulpified and where the blood and urine are extravasated into the surrounding tissues, there will develop in the course of hours, days or weeks, a tender tumor in the loin, accompanied by the constitutional signs and symptoms of hemorrhage and followed later by septic symptoms. In these cases the accident will usually have been followed by marked shock and the diagnosis of rupture of the kidney will sooner or later become quite plain.

The rarer group of cases accompanied by laceration of the peritoneum and extravasation of blood and urine into the peritoneal cavity will be attended by the symptoms of peritoneal irritation, and if not operated upon at an early date, by peritonitis. In the last group the general signs and symptoms of any severe intraabdominal injury will be present and will usually furnish adequate indications for immediate operation.

A small group of cases occur of multiple injuries, or of injuries in which the exact site of the lesion cannot be discovered, either because localized evidences of contusion are wanting, or because the patient is unconscious; in these, it may be necessary to distinguish whether the blood comes from the bladder or the kidney. This is sometimes possible. Usually in bleeding from the kidney, the urine is equally mixed with blood; if, however, the bladder is the source of hemorrhage, the *last* portion of the urine passed often contains more blood than the *first*. The following procedures are sometimes useful in the differential diagnosis; if there is reason to suspect that the bladder is actually ruptured they had better be omitted.

If the bladder be washed clean with salt solution and the hemorrhage comes from the kidney, further immediate washings will return clear, or but slightly stained with blood; if the blood comes from the bladder, repeated washings will usually appear blood-stained, since the mechanical distension of the bladder with fluid will usually be sufficient to keep up, or inaugurate fresh bleeding. The same may be true in some cases of rupture of the membranous urethra. The cystoscope will enable us to clear up the diagnosis in some doubtful cases. If the hemorrhages comes from the bladder, the fluid medium will usually become opaque at once; if from the kidney, gushes of bloody urine, in case the bleeding is still going on, may be seen proceeding from the orifice of one or other of the ureters; or, a clot may be seen adhering to the orifice of one ureter. If the bleeding has permanently or temporarily ceased, the cystoscopic field may be so clear as to enable us to eliminate the bladder as a source of blood. It is to be borne in mind that the mere presence of a blood clot overlying one ureteric orifice is not proof positive that the blood has come down the ureter. In order to be distinctive we must be able to recognize that the clot protrudes from, or is actually attached to, the orifice of the ureter.

Subcutaneous injuries of a kidney, containing a large or rough stone, or the seat of a new growth, or of polycystic degeneration, though of slight severity, may cause hematuria from contusion or rupture of the organ; and, in such cases, the actual condition will not be recognized until the kidney is exposed through an incision.

A case illustrating one of these conditions came under my observation on Sunday, May 23, 1909, with the following history:

He was a man, aged 34 years, who had enjoyed throughout his life reasonably good health and had never suffered from any symptoms referable to his genitourinary tract. He was said to have had an attack of malarial fever, acquired during a visit to Cuba. During the past few years he has had, from time to time, attacks of pain referred to his epigastrium, for which he had consulted several physicians, who had made a diagnosis of gastric dyspepsia of indeterminate causation. The attacks were not very severe and were never referred to the region of the kidney.

On Saturday evening, May 22, 1909, the day before admission to the hospital, while about to de-

scend the stairs of an elevated railway station in Brooklyn, he caught his heel in the rubber matting and pitched headlong down a flight of steps. He was rendered unconscious by the fall, was picked up by a patrol wagon, and taken to the police station. He regained consciousness in a few minutes after he was hurt, and felt well enough in a short time to proceed to his home in New York. He received several contusions of the face and scalp, but no other injuries of which he was conscious except that he suffered a moderate amount of pain in the left loin. He went to bed and slept fairly well. The next morning he observed that his urine was bloody, and at about the hour of three in the afternoon he came to the hospital in a cab. I saw him about an hour later.

He was a fairly well-nourished individual, rather slender than stout. He said that for some time he had had a chronic cough. There were no external evidences of injury except the contusions of the face and scalp and a small abrasion in the mid-axillary line opposite to the seventh rib upon the left side. Urine passed after he entered the hospital was of a deep port-wine color. The heart and lungs appeared to be normal. His temperature was not elevated, his pulse was 90. He complained of a sense of distention and soreness in the left side of the abdomen and loin, just below the ribs.

Physical examination showed that the left loin was occupied by a considerable tumor mass extending downward to the umbilicus and nearly to the median line in front. The mass extended upward beneath the ribs. It was flat on percussion, and the colon, displaced somewhat toward the inner side, lay in front of it and produced an area of tympanitic resonance. The left side of the abdomen over the tumor was markedly rigid, and quite tender. The patient looked rather pale and anemic, and a diagnosis was made of a rupture of the left kidney with a large perirenal retroperitoneal hematoma.

The patient's condition being good I did not operate upon him until the following morning. Under gas and ether, an incision was made parallel to the ribs upon the left side, beginning at the outer border of the rectus in front, two inches below the costal margin and extending backward and outward slightly convex downward to the outer border of the erector spinæ muscle. Upon opening the loose perirenal fat, a hematoma of moderate size was entered; but further explorations showed the presence of a large polycystic kidney, which was ruptured horizontally at the junction of the upper with the middle thirds of the tumor. The pictures shown are about one-half the size of the organ. The rupture was on the anterior aspect of the kidney and almost completely separated it into two parts.

Upon palpation of the opposite kidney through the wound it appeared to be of normal size and consistence. The kidney upon the left side was removed without difficulty and with trifling hemorrhage. The ureter appeared normal and the renal artery and vein were of about normal size. The wound was sutured, with a suitable gauze drain introduced at its posterior angle. The patient did not suffer from shock and continued to pass abundant urine. The wound healed *per primam,* except for the drainage opening.

Upon the third day after the operation he passed seventy-two ounces of urine, three weeks after the operation he was passing from forty to fifty ounces a day. The urine, however, showed evidences of a moderate nephritis. It was of a specific gravity of 1.012, contained a perceptible trace of albumin, together with granular and hyaline casts. He had moderate cough, with very little expectoration in which no tubercle bacilli were found. The probabilities seem that he will survive, but whether or not his remaining kidney will continue to functionate, whether he will die eventually of nephritis, or, on the other hand, whether the organ will undergo a similar cystic change, it is at present impossible to say.

The interesting features of the case were that the tumor had never produced any definite symptoms, and that it should only have been discovered after its accidental rupture, the latter accident being, so far as I am aware, unique.*

In the cases attended by profuse bleeding, the bladder may have become filled with clots, there will be intense pain in the bladder with tenesmus, and often complete inability to urinate. The later septic complications of subcutaneous ruptures of the kidney rarely lead to diagnostic error.

(b.) *Open Wounds of the Kidney.*—These may be divided into I, Incised, stab, and puncture wounds with or without protrusion of the kidney; and II, Gunshot wounds.

Diagnostic errors should be infrequent in cases of incised, stab and punctured wounds of the kidney. If the wound enters a calyx, or the pelvis, immediate hematuria will usually render the diagnosis certain, urine, or urine mixed with blood will escape from the external wound, or if that be very narrow, will form a retroperitoneal tumor in the loin, or, if the peritoneum be opened, will soon produce signs and symptoms of peritoneal irritation. In many instances the necessary exploration of the wound for the control of hemorrhage, drainage, etc., will permit the wound of the kidney to be felt and seen.

It is well to bear in mind that wounds which do not enter a calyx or the pelvis, or at least enter a pyramid, will not, as a rule, be accompanied by macroscopic hematuria. If the wound passes through the anterior abdominal wall and injures other viscera, or through the pleural cavity and diaphragm, the diagnosis of kidneys injury in the absence of hematuria is not apt to be made at once, unless the abdomen is explored through an incision. Wounds in the loin accompanied by protrusion of a sound or injured kidney offer no diagnostic difficulties.

Gunshot Wounds.—Gunshot wounds of the kidney unaccompanied by injuries of other important viscera are rare. The liver, stomach, intestines, pancreas, lung and pleura, and the spinal vertebræ and cord, one or several of them, are often wounded, therefore, shock, intraabdominal bleeding and peritonitis are common results. As in other open kidney injuries hematuria and the escape of urine from the external wound are the cardinal signs. The latter, owing to the small size of the wounds in the skin, is often absent.

Primary bleeding has been slight in a large proportion of uncomplicated gunshop wounds of the cortex, secondary hemorrhage at the end of the week or more, has been rather frequent, and in many instances severe. On the other hand bullets which cut the renal artery, or vein, or both, bleed so rapidly that immediate operation offers the only

*Since the above was written, eight months ago, the patient has apparently made a complete recovery. He has resumed his work and feels well. There are evidences of a slight nephritis.

hope of saving life. As in subcutaneous injuries, the symptom hematuria, may be slight or absent when the bullet wounds the cortex merely, or when the ureter is cut.

The path of the military rifle bullet through the tissues is straight; so that in perforating wounds of the trunk, injury of the kidney might be inferred with probability on anatomical grounds. When a bullet enters from in front other viscera are almost sure to be injured, and in these cases shock, hemorrhage and peritonitis produce symptoms which may overshadow the injury of the kidney.

In one case upon which I operated the patient was shot through the left chest; his history was as follows:

G. R., a well-nourished, vigorous-looking man in the prime of life, was admitted to the New York Hospital on the afternoon of November 24, 1904. Twenty minutes before admission he had been shot in the chest with a .32 caliber revolver at close range. On admission his face was pale and anxious. Extremities cold. Pulse rapid and feeble. Rectal temperature, 99.6°. Respiration, 28, and labored. There was a bullet wound in the seventh intercostal space on the left side, in the anterior axillary line. There was no hemoptosis or external bleeding. The abdomen was moderately distended, tympanitic, and rigid. There was absence of liver dullness. The rigidity was most marked in the left hypochondrium. The patient had vomited partly digested food. I saw him a few minutes after his admission, and operated upon him under ether, less than an hour after the shooting. Abdomen opened along outer edge of left rectus muscle. Free blood, air, and a small amount of intestinal contents in the abdominal cavity. Upon retracting the wound edges and pushing aside the stomach a perforation could be seen in the diaphragm about four inches from the middle line, through which air and blood rushed in and out during respiration. There was a single contused wound of the transverse colon which had not opened the gut. There were two perforations in the jejunum about seven inches from its junction with the duodenum. The wounds in the gut were sutured and the abdomen washed. Efforts to close the wound in the diaphragm had to be desisted from on account of the bad condition of the patient. No active bleeding into the belly, other than from the diaphragm, was observed. Stimulation, drainage, closure of the abdominal wound. Patient rallied from shock, but had a gradually increasing abdominal distention. Continued vomiting, finally, dark brown in color and with a foul odor. There was marked dyspnea and the physical signs of hemopneumothorax on the left side. On November 25th the urine contained a moderate amount of blood. His temperature and pulse gradually rose, and he died November 26th at 9.30 A. M. The autopsy showed, in addition to the injuries described, a wound of the lower pole of the left kidney in which the bullet was lodged. There was a moderate amount of blood-stained fluid in the peritoneal cavity. The intestinal wounds were water-tight. The wound of the kidney was not discovered at the time of operation, though failure to discover it had nothing to do with the fatal result.

2. *Movable Kidney.*—Errors of diagnosis in cases of movable kidney in so far as they relate merely to the discovery of the fact that the kidney is loose and unduly mobile are scarcely likely to occur. On the other hand errors quite frequently occur in attributing pain, digestive disturbances, nervous symptoms, etc., to the mere mobility of the organ. No doubt every surgeon has operated in the hope of curing such symptoms by fixation of a movable kidney or kidneys only to be disappointed in the result. It is difficult to lay down any fixed rules for avoiding such errors. If the symptoms subside or disappear from prolonged rest in bed, elevation of the foot of the bed, or even a partial "Trendelenburg's posture" it is probable that fixation of the kidney may effect a cure. If, on the other hand, the patient suffers from general enteroptosis and is markedly neurasthenic or hysterical, and in cases where severely painful crises are absent, and where there are no changes in the quantity and quality of the urine during and after the attacks of pain, the surgeon will do well to be very cautious in advising operation.

3. *Hydronephrosis.*—In considering the errors which may occur in the diagnosis of hydronephrosis it is to be borne in mind that dilatation of the kidney may be produced by urinary obstruction situated anywhere between the orifice of the fore-skin and the calyces of the kidney. Further, that, in the cases due to obstruction at any point lower than the ureters before they enter the bladder, or even above this point, the disease may be bilateral. Stricture of the urethra, prostatic obstruction, tumor of the bladder, intrapelvic tumors, tumors of the uterus, etc., must be sought for and eliminated before we can be certain that but one kidney is affected and that our measures for relief should be directed to the kidney itself, or to the ureter of one side, rather than to the urethra, the bladder, the prostate, etc. I cannot take the time or space to enumerate and describe the causes and varieties of hydronephrosis, suffice it to say, that the causes are very varied and are due to either congenital or acquired obstructions. That the closure of the ureter may be partial and continuous or intermittent; each of these latter groups producing more or less characteristic symptoms and signs, and that the causes may be intrinsic or extrinsic. The lesions with which hydronephrosis is most likely to be confounded are cystic tumors of the liver, pancreas, and spleen, more rarely with cystic dilatation of the gall-bladder. Some years ago I made an error in diagnosis mistaking a cyst of the tail of the pancreas for a closed hydronephrosis. Had ureteral catheters been passed, the error, although of no moment from a practical point of view, would have been avoided. In this case the tumor grew from the tail of the pancreas and presented exactly like a hydronephrosis in the left flank. The tumor was tense and elastic, flat on percussion, and was crossed in front by the colon. Cysts of the mesentery or any other cystic retroperitoneal growths presenting in the flank may be differentiated from a hydronephrosis by catheterizing the ureter on the affected side. If we are dealing with a closed hydronephrosis the catheter will pass either not at all, or only for a short distance. In the latter instance a dry tap will result. If the tumor is cystic in character but not connected with the kidney the catheter will deliver urine from both kidneys, and such urine may or may not be normal. The size and consistence of a cystic tumor will remain unchanged. In the female, a hydronephrotic kidney may sometimes be mistaken for an ovarian cyst. The differential points are as follows: A large ovarian cyst occupies a nearly central position in the abdomen; a hydronephrosis, even though it may extend be-

yond the median line, does not occupy a strictly central position in the belly. The inflated colon lies in front of a hydronephrotic sac, in all but enormous dilatations, when it may lie to the inner side. Ovarian cysts only very rarely have intestinal coils in front of them. The relations and attachments of the tumor to the uterus and its adnexa may sometimes be made out in doubtful cases by seizing the cervix with a vulsellum forceps and drawing it strongly downward toward the vulva; the uterus and adnexa are then palpated per rectum and their mobility and freedom from attachment to the tumor or the contrary may thus be determined. In some cases a calculus may be felt in the lower end of the ureter, making the diagnosis of hydronephrosis almost certain. Hydronephrosis of a congenitally misplaced kidney will, in the absence of a history of urinary symptoms, nearly always lead to an error in diagnosis. I have myself made this error in four cases. Hydronephrotic kidneys, if not of enormous size, will usually be mobile laterally, sometimes vertically as well, whereas a congenitally misplaced kidney is firmly fixed. Injection of the ureters with argyrol solution and an *x*-ray picture may clear up the diagnosis. I have never personally mistaken a distended gall-bladder for hydronephrosis. A very large thin-walled sac has been mistaken for ascites; the two conditions may of course co-exist. Echinococcus of the liver may be mistaken for hydronephrosis; the former has usually a very long history, is immovable, and can in no wise be differentiated from the liver. If movable, echinococcus cyst of the liver may have a vertical respiratory mobility. Hydronephrosis of the kidney, if not enormous, will usually be movable laterally, sometimes vertically, and percussion and palpation will usually permit differentiation from the liver.

It is often impossible to determine before operation whether a hydronephrotic sac is infected or not. In the presence of chronic septic symptoms such infection is probable, but in all closed hydronephrotic sacs with thickened walls chronic suppuration may occur without much absorption, and septic symptoms may be entirely absent. Certain other conditions may be mistaken for hydronephrosis. Perinephric suppuration is usually rather an acute process, is accompanied by marked sepsis, fever, an accelerated pulse, an increase in relative number of polymorphonuclear leucocytes with blood cells, etc. The local signs of acute inflammation are present in the loin, or soon develop pain, tenderness, later redness of the skin. The swelling is not a sharply circumscribed tumor but a hard or boggy diffuse infiltration.

A very important diagnostic error may be committed in those cases of hydronephrosis due to the presence of a stone in the ureteric pelvis or in the ureter. The position of the stone should be determined if possible before any operation is undertaken. This can be accomplished in many instances by a series of *x*-ray pictures. In some it cannot. In my experience, in cases of intermittent hydronephrosis due to the presence of stone or stones, the calculi have acted as a ball valve and have lain in the dilated pelvis or just at the beginning of the ureter. When the stone lies further down the ureter and causes hydronephrosis, the symptoms are more apt to be continuous and the obstruction constant whether complete or incomplete. The *x*-rays and the passage of styletted ureteral catheters and of wax-tipped bougies may sometimes enable us to locate the position of the stone. Rectal and vaginal palpation should not be omitted. It would of course be a grievous error to open and explore a hydronephrotic kidney still, perhaps, capable of functionating when the seat of the obstruction, stone, or other was situated far down the ureter.

4. *Suppurative Lesions of the Kidney.*—Unilateral hematogenous pyogenic infection of the kidney may escape recognition during its early stages on account of the intensity of the general septic symptoms and the absence of distinctive signs pointing to a kidney lesion. While this is more particularly true of the bilateral cases, the same may be said of the unilateral infections, though to a less extent. The changes in the urine may be slight, though albumin, pus, and blood are usually present, the pus and blood may only be discovered by microscopic examination. The cystoscope will usually reveal swelling of the papilla of one side, sometimes redness and ulceration, or injection of the entire trigone. Ureteral cathterization will usually show the presence of albumin, pus, and blood in the urine of the infected kidney.

There will nearly always be pain sometimes referred to the loin, but rarely so severe as in the attacks of renal colic caused by stone. In other cases the pain will be referred to one side of the abdomen, or to the iliac fossa, so that if upon the right side, a diagnosis of appendicitis may be made. The pain may be central in the abdomen or without definite localization. There will be tenderness upon palpation of the kidney region in front, and always behind over the last rib, or below the rib at the outer border of the erector spinæ muscle. There will always be abdominal rigidity, often very marked over the affected organ. This sign has in my experience been useful in differentiating a mere pyelitis from a suppurative lesion of the kidney. Palpable enlargement of the kidney will usually be absent during the early stages of the disease for, although the kidney is swollen, abdominal rigidity will prevent its recognition except under a general anesthetic, or, the swelling may be confined to the upper pole of the organ and thus be entirely out of reach. In thin and flabby subjects it may be possible to feel that the kidney is increased in size.

The group of signs and symptoms briefly outlined together with the general symptoms of sepsis have been in my experience sufficient justification for exposing and exploring the kidney. The early diagnosis of these cases is particularly important since, if untreated, the other kidney will often be secondarily involved.

Subacute Cases.—In another group of cases primary pyogenic infection of the kidney runs a far less acute course. The onset may be insidious, there may be no pain, or only dull pain in the loin, or a sense of dragging and fullness. Continuous or intermittent pyuria may be the only local sign to point to disease of the genitourinary tract; or, these patients will suffer from frequent and painful urination. They are often treated during long periods for cystitis. In a large proportion of these cases symptoms of chronic sepsis are more or less marked. These patients have an evening rise of temperature, occasionally chilly sensations, or chills and sweating. They become anemic, suffer from loss of appetite and loss of flesh. In some cases constitutional disturbances—fever, etc.—are associated with attacks of renal pain and with retention of urine and pus in the affected kidney. If during these attacks the patient passes clear and normal urine, followed by marked pyuria and synchronous subsidence of

fever, etc., the diagnosis of a unilateral kidney or ureteral lesion is quite plain. During the period of retention there will usually be tenderness over the kidney and in some cases a palpable tumor. A somewhat similar series of events may occur when an abscess in the kidney ruptures into the renal pelvis. The patient may have suffered from pain and tenderness in the kidney region with more or less marked sepsis with or without palpable tumor; suddenly a very marked pyuria will occur, often with temporary abatement of the septic symptoms, and diminution in the size of the tumor—if such existed.

Secondary stone formation is very common in these cases, and in my experience more mistakes in diagnosis are made in these than in any other surgical lesion of the kidney. These patients are often treated for cystitis and for stricture of the urethra for years. A very important thing to bear in mind when deciding for or against operation is that septic nephritis of considerable severity may exist in one kidney without constituting an absolute contraindication to the removal of its fellow. I have reason to believe that in many cases operation is needlessly refrained from because the urinary findings indicate a chronic nephritis of the better kidney. Some of these cases can be restored to health by the removal of the suppurating kidney. Many cases might be quoted in which an apparently severe nephritis caused by chronic suppuration in any part of the body has entirely disappeared after the septic focus has been removed by operation.

Pyonephrosis.—In typical cases of pyonephrosis and of infected hydronephrosis the physical signs, the history, the palpable enlargement of the kidney, the *x*-ray examination, the pyuria, offer such a distinctive clinical picture that diagnostic errors should be infrequent, and yet as in the preceding group the condition of the kidney may pass unrecognized for many years. Many of these patients are treated for cystitis or other bladder lesions.

5. *Tuberculosis of the Kidney.*—In no other surgical lesion of the kidney is an early diagnosis more important than in tuberculosis. Experience shows that in a very large proportion of these cases the disease is confined at first to one kidney, the removal of which at an early period will result in cure. Failure to make an early diagnosis in these cases depends upon several conditions—first, many patients with primary renal tuberculosis in its early stages have the appearance of good health. Every young person who comes to us complaining of polyuria usually noticed at night, and in whose urine we find a moderate amount of pus, without a history of gonorrhea, should be regarded as a possible subject of kidney tuberculosis, and the diagnosis of the case should command our earnest, and, if necessary, prolonged attention. An early positive diagnosis is frequently difficult, sometimes impossible, for four additional reasons, namely: 1. The difficulty of finding and identifying tubercle bacilli in the urine. 2. The complete latency of the disease in many cases during its early stages. 3. The frequency with which the early symptoms are referred to the bladder, leading to a false localization of the disease. 4. The protean character of the early symptoms when they are referred directly to the kidney—thus, renal colic and hematuria may usher in the tuberculous infection of the kidney, and lead to the probable diagnosis of renal calculus. In the later stages of the disease, mixed infection still further obscures the diagnosis, though, at this time, the presence of a surgical lesion of the kidney can usually be established without much difficulty.

Many of the errors in the diagnosis of pyogenic and tuberculous infection of the kidney may be avoided by bilateral ureteral catheterization, by repeated search for tubercle bacilli in the urine, and the inoculation of guinea pigs. There will, however, remain a considerable number of cases, notably in males where for one reason or another catheterization of the ureters is impracticable, and in these we may be unable to assure ourselves positively of the condition of each kidney. In my experience, also, search for tubercle bacilli in the urine has been negative in a large proportion of cases of tuberculosis of the kidney. Search may be unavailing 1, When mixed infection with pyogenic germs is present. 2. When the tuberculous lesion is confined, as it often is in early cases, to the cortical portion of the kidney. 3. When the ureter is obliterated or plugged.

In cases attended by early ulceration of the apices of the pyramids, tubercle bacilli will usually be found in considerable numbers early in the disease. In case one kidney is entirely destroyed by tuberculous infection and its ureter is plugged, or obliterated, the mistake has sometimes been made of removing the other kidney, which, while tuberculous was still functionating sufficiently to keep the patient alive. I have seen this fatal error made in two cases; one was a man, the other a woman. In neither was catheterization of the ureters successful. It is to be borne in mind that mere palpation of the kidney through a wound does not permit an accurate conclusion as to its condition. In the absence of data derived from the urine, nothing short of visual inspection of the organ will suffice.

Chromocystoscopy following the administration of indigo carmine subcutaneously (4 c.c. of a 4 per cent. solution) is sometimes a useful aid in diagnosis where ureteral catheterization is impracticable. The functional activity of the supposedly healthy kidney in the given case is to be determined by estimation of the urea. An average daily excretion below 15 grams is usually regarded as pointing to a grave functional incapacity on the part of the kidneys. The phloridzin test is sometimes useful.

6. *Renal Calculus.*—In spite of the great value of the *x*-rays in the diagnosis of stone in the kidney, more mistakes, positive and negative, are probably made with reference to this condition than is true of any other surgical lesion of the kidney. The mistakes in my experience may be divided into several groups. A negative diagnosis of renal calculus may be made by the *x*-rays, whereas a uric acid stone is sometimes present in the kidney. In my experience such stones cannot be shown with certainly in an *x*-ray picture. Other stones may be missed, if small, in case the patient is very stout, or, in case the *x*-ray technique is imperfect. This last error is made with decreasing frequency as *x*-ray technique and apparatus are perfected. In a certain number of cases kidneys are explored in search of stone, and no stone is found. This may depend upon incorrect interpretation of the *x*-ray picture, an indefinite shadow upon the plate is regarded as that of a stone. This mistake will most often be made when the *x*-ray pictures are of inferior quality, though it may be due to the fact that the bowels have not been thoroughly empty when the picture was taken. The error may be avoided by refusing to make a diagnosis from *x*-ray pictures of poor quality and by having two or more pictures taken of

each case, so that the shadow of the stone, if such there be, can be positively identified. Another error occurs occasionally, when, with a very definite history of stone, the patient has unknowingly passed one or more calculi per urethram, and the surgeon operates in spite of negative *x*-ray findings in the belief that the stone is either uric acid, or that numerous minute calculi exist in the renal pelvis, a not very rare condition which, in my experience, cannot be diagnosticated with certainty in all cases by means of an *x*-ray picture. In these cases the shadows cast by the minute calculi are faint, diffuse, and without definite outline, and this group of cases again may lead a cautious surgeon to refrain from operation, whereas it is distinctly indicated. In these cases, however, the clinical history will usually be very characteristic. The changes in the urine will be quite marked, and there will usually be a history of the passage of gravel as well as of the recurrent attacks of renal colic.

The typical kidney colic is characterized by a sudden onset, and is of excruciating character; it is felt in the kidney region affected, along the course of the ureter, sometimes in the bladder, the testes, and external genitals. The pain may also radiate upward into the shoulder or down the thigh along the distribution of the anterior crural nerve. The pain is sometimes accompanied by vomiting, great prostration, sweating, by a constant desire to urinate, and in some cases by general convulsions. The attack may last for a few minutes, for hours, or for several days. The pain generally subsides suddenly, leaving the individual quite free from discomfort.

This typical history of an attack of renal colic is, clinically, the exception rather than the rule. Any one of the characteristic symptoms may be absent. The pain may be referred in such a manner as to lead to suspicion of disease of a different character. The symptoms may point to acute gastrointestinal disturbance. The pain may closely resemble an attack of biliary colic. If the pain is localized in the epigastrium, is a general abdominal pain, or is felt chiefly on the right side of the abdomen, low down, it may be mistaken for disease of the appendix. There are numerous instances in which kidney stone has been mistaken for scoliosis and for tuberculous disease of the bodies of the vertebræ.

It is also to be remembered that a number of conditions, other than stone, affecting the kidney may give rise to precisely the same train of symptoms. The invasion of the kidney structure with tuberculosis, with its accompanying congestion and tension of the kidney capsule, may produce identical symptoms, and be accompanied by characteristic hematuria. A new growth into which a hemorrhage takes place may exactly simulate a renal colic. It is asserted by several authorities on the subject, although denied by others, that the pain may be located upon the opposite side of the body. My own observation supports the affirmative view. Hemorrhagic pyelitis may give rise to symptoms precisely the same. Kinks in the ureter, in cases of movable kidney, may give rise to similar attacks. In general, any condition which produces a sudden increase in the intracapsular tension of the kidney or which obstructs the ureter may accurately simulate an attack of renal colic, an intraabdominal tumor, or an aneurysm—by pressure, for example.

There remain to be considered the very large group of cases in which the stone remains, so to speak, quiescent, giving rise to no symptoms at all, or at most to a slight amount of discomfort from time to time, or to symptoms hardly to be differentiated from those of ordinary functional gastrointestinal disturbance.

In another class of cases the typical symptoms of renal colic are entirely wanting, and the patient may suffer from constant or intermittent pain, sometimes referred to the region of the kidney, often to the bladder, and not infrequently to distant parts of the body, as, for instance, the sole of the foot. A large number of these cases are treated for bladder disturbance, none of the symptoms being referred to the kidney.

Calculous Anuria.—A patient who suffers from kidney stone may suddenly be seized with suppression of urine. If the other kidney is absent, destroyed, or seriously diseased, or if both ureters are obstructed at the same time, the condition will usually end in death in a few days, unless relieved by operative removal of the stone obstructing the ureter, or unless, as sometimes happens, the obstruction is partly or entirely overcome by natural means. If the other kidney is sound it usually continues its function. Sometimes a reflex anuria, usually of a temporary character, may occur in this sound kidney also. In fact, it is probable that such reflex anuria in a sound kidney rarely, if ever, endures to a fatal issue.

The symptoms of the onset of urinary suppression from calculus differ to some extent from the ordinary symptoms of uremia. At the beginning there is usually pain, referred to the kidney region or to the lumbar region, and down the course of the ureter. The pain may last throughout the attack, or more often will subside after hours or days. Many of the symptoms may be referred to the bladder, as in an ordinary attack of renal colic. When the obstruction is absolute, no urine may be passed after the beginning of the attack. If incomplete or intermittent, oliguria may alternate with polyuria. These are the cases in which hydronephrosis develops. The suppression is rarely so absolute as in ordinary cases of uremia, and, usually, small amounts of urine of low specific gravity will be voided, even though the case is to end fatally. In case the useful kidney is hydronephrotic a certain tolerance appears to be established; and even if the obstruction is not overcome, death may be delayed for many days. When uremic symptoms develop, they resemble those accompanying other forms of suppression, except that vomiting is more common and diarrhea less so.

Changes in the Urine.—The evidences furnished by the urine are valuable, although there are no data to be obtained from the urine, which enable us to make a certain diagnosis of kidney stone. The urine may be entirely free from abnormal ingredients. In certain cases the examination of the urine suggests merely a hyperemia of the kidney. The urine frequently contains blood in small amount, constantly or only at intervals. The blood in many cases is only discoverable under the microscope. There will sometimes be a quantity of albumin present in the urine, slightly in excess of the amount of blood or of the number of pus cells, if such are present. Sharp, and even dangerous, hemorrhage may occur, but such cases are the exception. The type of bleeding which furnishes us with the strongest evidence of the presence of calculus is small in amount and frequently microscopic. The number of blood cells present in the urine is often increased by muscular exertion, and entirely disappears when

the individual is kept quiet. When the hemorrhage is coincident with an attack of renal colic the bleeding usually continues for hours or days after the colic has subsided. Blood casts of the renal tubules do not occur, nor are blood casts of the ureter at all common. When the hemorrhage is severe, we must depend upon other physical signs and symptoms to exclude the presence of a malignant growth, an invasion of the kidney with tuberculosis, or the presence of a hemorrhagic pyelitis. A moderate increase in the number of leucocytes contained in the urine, or even a mild catarrhal pyelitis, may exist without infection.

In the absence of lesions of the lower genitourinary tract, the presence of a small quantity of blood, a trace of albumin, a moderate number of leucocytes in the urine is, when combined with attacks of renal pain, in the absence of tubercle bacilli and failure to appreciate a notable enlargement of the kidney on palpation, and especially if there is a previous history of the passage of calculi, strong presumptive evidence of the presence of stone.

When infection of the kidney has taken place and the urine is loaded with the products of inflammation, it is scarcely possible by urinary analysis to say whether the primary cause of the trouble is stone or some originally infections process; indeed, a stone or stones are often found in the pelves of pyonephrotic kidneys, apparently as a secondary condition to the suppurative nephritis, and also in tuberculous kidneys in which the secondary purulent infection has occurred, stone is not very rare.

These secondary cases of renal calculus present themselves to us more commonly as cases of pyonephrosis, perinephritic abscess, or other serious destructive lesion of the kidney, in which the stone plays a subordinate rôle from a pathological as well as from a diagnostic point of view. In those cases of primary calculus where infection occurs, a series of signs and symptoms are exhibited, complex in character, and due in part to the presence of stone; either set of signs and symptoms may predominate in any variety of prominence.

Physical Signs and Symptoms To Be Observed by Palpation.—Manifestly the only positive signs of the presence of kidney stone discoverable by palpation are the actual appreciation of the stone under the examining fingers or a sensation of grating obtained by moving one stone upon another. Such signs are rarely observed, and only in cases presenting stones of unusual size or in the persons of individuals unusually flabby and with thin abdominal walls. Such cases must of necessity belong to the surgical rarities, and although occasionally observed and reported by surgeons, these signs can scarcely constitute a common means of diagnosis.

A physical sign to which many surgeons have attached much importance is the occurrence of pain elicited by a light, quick blow upon the last rib of the affected side, or localized tenderness on pressure just below the last rib. In the absence of pronounced changes in the urine and of other signs of serious deorganization of the kidney, this sign is often given a high diagnostic value, when taken in connection with subjective symptoms, such as commonly accompany the presence of a stone in the kidney. Since the presence of a stone in the renal pelvis is not incompatible with a kidney normal in size, shape, and position, the existence of a tumor of any description corresponding to the situation of the kidney, or the absence of such a tumor, is not necessarily significant of the presence, or, on the other hand, of the absence, of stone. Stone impacted in the lower end of the ureter may occasionally be felt *per rectum* or *per vaginam*.

The Cystoscope and Ureteral Catheter.—The cystoscope and ureteral catheter sometimes afford useful aid. A stone projecting through the opening of the ureter into the bladder can be seen through the cystoscope. The ureteral catheter, when passed into the ureter, may meet with obstruction, and such obstruction may be due to stone. A positive diagnosis even is possible, and has been made by inserting a wax-coated bougie into the ureter. The bougie coming in contact with the stone was moved back and forth, and scratch marks were found upon the surface of the wax, thus showing the presence of some hard, rough substance (Kelly). The general conclusion must, then, be drawn, that in by far the largest proportion of cases no positive diagnosis of renal calculus can be made by the ordinary methods of examination. In many cases the operative exposure and examination of the kidney is necessary.

Errors and Limitations in the X-ray Diagnosis of Renal Calculi.—With the best apparatus and expert technique it is probably possible at present to detect stones in the kidney and ureter in nearly all cases, provided the stones do not consist of uric acid merely. The difficulties in the way of a positive diagnosis are, however, considerable when the patient is stout, when the stones are small; unless a negative of very good quality is obtainable, stones which are present may be missed, or, on the other hand, a diagnosis of stone may be made when no stone exists.

In my opinion it is unjustifiable to make a positive diagnosis of stone in the kidney or ureter, unless the shadow produced by the stone is absolutely distinct, and is found to be present in successive plates, preferably taken at intervals of several days. If these conditions are fulfilled, mistakes will rarely occur; still, errors are possible. A shadow may appear upon the photographic plate which is really not a urinary calculus; such may be scybalous masses, vein stones, prostatic calculi, calcareous plaques in the muscles and ligaments, calcified mesenteric or retroperitoneal lymph nodes, as well as other similar concretions. The passage of styletted ureteral catheters and their radiography in situ may prevent such errors, or, in some cases, it may be possible to inject through the catheters argyrol solution, thus filling the ureters and their pelves with a liquid rather impervious to the rays; the negative then produced by an *x*-ray exposure will show the outline of the ureters and pelves quite plainly, and, of course, shadows which do not lie in the ureteric paths do not have their home in the genitourinary tract.

As already noted, minute gravel distributed through the calyces, pelvis, and ureter may cast such faint or diffuse shadows as to escape notice. As mentioned in one of the case histories, very numerous calculi may, in rare instances, cast so diffuse a shadow as to escape notice, even in a fairly good negative.

When the apparatus used is imperfect and the quality of the *x*-ray pictures is not the best obtainable, the number of diagnostic errors are, in my experience, enormously increased. The day is past when the average surgeon can do his own *x*-ray work. The best *x*-ray apparatus is so expensive and cumbersome and the time, care, and skill nec-

essary for its successful use are so great, that the best *x*-ray work to-day can scarcely be done except by the specialist or in a large hospital.

Even after the presence of a stone in the kidney has been demonstrated by the *x*-rays, it may be quite hard to find it after the kidney is exposed. A case of this kind came under my observation a few weeks ago. A boy aged thirteen years entered the hospital, in my service at the New York Hospital. The *x*-ray showed very clearly the presence of a small stone in the pelvis of the right kidney. Upon exposing the kidney, the stone was readily felt at the junction of the pelvis with the ureter. In order to make access to the stone easier, the kidney was freed from its fatty capsule and delivered from the wound. It was my intention to incise the pelvis, remove the stone, sew up the cut in the wall of the pelvis, and put the kidney back in place. The stone, however, could no longer be found; it had slipped back into the uppermost of the calyces, where it was found and extracted, only after incising the convex border of the organ and searching with a finger in the pelvis and several calyces, one after the other. Had no *x*-ray picture been taken, or had the shadow of the stone been doubtful, and had I not felt it very plainly earlier in the operation, I should probably have assumed a diagnostic error and desisted from the rather prolonged search.

In a subsequent paper I shall consider the diagnostic errors which may be made in perienal inflammations, in congenital defects and displacements of the kidney, in tumors of the kidney, and shall also consider the diagnostic errors in those diseased conditions where hematuria is the most marked symptom.

MEDICAL PRACTICE LAWS.*

A REVIEW OF CERTAIN PHASES OF THE LEGAL REGULATION OF MEDICAL PRACTICE.

By FLOYD M. CRANDALL, M.D.,

NEW YORK.

"WHEREAS, many ignorant and unskilled persons in physic and surgery, in order to gain a subsistence, do take upon themselves to administer physic and practice surgery in the City of New York to the endangering of the lives and limbs of their patients, and many poor and ignorant persons inhabiting said city, who have been persuaded to become their patients, have been great sufferers thereby. For preventing such abuses for the future, be it enacted that no person whatever shall practice as physician or surgeon before he shall first have been examined and after due examination of his learning and skill, shall be approved and admitted to practice."

These words introduced the first medical practice law of New York, that of June 10th, 1760, and constitute an admirable statement of a principle which has animated every law regulating the practice of medicine in New York during the 150 years since it was enunciated. In other words, the people of New York for at least a century and a half have recognized the fact that uneducated doctors are a menace to the community. It is, moreover, a demonstration of the old saying that there is no new thing under the sun. Our modern medical examining board had its prototype in Colonial New York one hundred and fifty years ago, for under the law of 1760 a medical examining board was appointed by the high officials of the city, including the Mayor, the King's Counselor, and the Judges of the high court. This law applied only to the City of New York, which then occupied but a small portion of Manhattan Island. In 1792, a law was enacted by the State Legislature renewing the colonial law and applying it to New York County. By its provisions two years of medical study were required of college graduates and three years of others. In 1797, the law was extended to cover the State. It is an interesting fact pointed out by Dr. Rogers that restrictive medical laws have always advanced in this State from the densely to the sparsely populated regions, from city to county, from county to State. We may take just pride in the fact that from colonial times New York City has evinced an appreciation of educated physicians.

The profession has passed through some grave periods of trial, however. One of these resulted in bringing about a material change in the methods of medical education and incidentally led to the founding of the first dispensary. On April 13th, 1788, some boys at play found the remains from a dissecting room. A crowd soon gathered and excitement rapidly spread throughout the town. Mobs formed in the streets, the houses of physicians were attacked, and many medical practitioners were injured. After the excitement had subsided, a feeling of antagonism was left against the profession, and to allay this a charitable enterprise was undertaken by several of the younger physicians. They induced the magistrates of the city to establish an apothecary shop to be maintained at public expense and gave their professional services to the sick poor. This was the origin of the New York Dispensary, the first in New York. Those connected with this dispensary began to deliver lectures and give instruction in medicine and at the end of three years sixty medical students were in attendance. The medical department of King's College (now the College of Physicians and Surgeons) had been organized in 1768 and the first degree of Doctor of Medicine was conferred in 1770. The rivalry between the Medical College and the Dispensary Clinic is not within the scope of this paper.

On April 4, 1806, the law was passed which looms up as a great landmark in the medical history of this State. Under its provisions the State and county societies were organized and clothed with great legal powers and were specially commissioned to "regulate the practice of physic and surgery in this State." So radical were its provisions that every legally qualified physician was declared by the courts to be "*ipso facto* a member of the medical corporation." Upon its enactment a contest for the control of the power to license medical practitioners was begun which lasted one hundred and one years. This contest has been admirably described by Dr. Howard J. Rogers, until recently the efficient First Assistant Commissioner of Education of New York, to whom I am indebted for many facts. During this period three forces contended for this control: first, the medical profession acting through its county and State societies; second, the medical colleges; third, the State of New York, acting through the Regents of the University. Under the law of 1806, the power to license practitioners was vested wholly in the county societies, the Board of Censors in each county being the examining board. This power was held without interruption by the county societies from 1806 until 1880. Exclusive

*Read before the Medical Society of the County of New York, February 28, 1910.

control, however, was held for only three years, for under the law of 1809 graduates of the State medical schools, on a degree granted by the Regents, were entitled to practise without examination by the censors.

During the earlier part of the nineteenth century, therefore, there were two sources from which a license to practise medicine emanated: (1) The diploma of the Regents of the University; (2) The license granted by medical societies to those who had studied with a licensed practitioner. As time passed the power of the societies diminished and that of the colleges increased. During this period the homeopathic and eclectic schools of practice developed and finally obtained the same rights for their State and county societies as that held by regular practitioners. Toward the latter part of the century there came to be, in fact, a triple control in the licensing power; that of the societies, the Regents, and the colleges. In 1872, a law was enacted by which the principle was first established that licenses might be granted by a State department, and not by those engaged in teaching and practising medicine. This principle was limited, however, and the other methods were continued in force. This was the first step toward absolute State control and completed an epoch which has now passed into history.

The second step toward State control was taken in 1880. By the law then enacted, the power was taken from the societies and the provisions of the act of 1872 were broadened and strengthened, thereby giving the Regents additional power. The character of the medical diploma as a license was still sustained, however. There was thus again established a dual control, but this time it was divided between the Regents and the colleges, instead of the Regents and the societies as in the first half of the century.

The third step toward State control was taken in 1890 when a law was enacted vesting the power to grant licenses to practice wholly in the Board of Regents and giving that Board the authority to determine the qualifications to be required of medical practitioners as regards preliminary and professional education. The medical degree was then deprived of all power as a license to practise. This was done with the willing consent of the colleges and the action was approved by all the schools of medicine. In 1893 radical changes were made in the medical practice act, particularly those portions defining preliminary and professional standards of education, but the principle of licensure was unchanged.

The fourth and final step toward State control was taken by the enactment of the law of 1907, by which the State, though its Education Department, was placed in full control of all matters relating to the practice of medicine, without regard to medical sects, societies, or colleges. Thus after continuous agitation for more than a century, the various forces seeking to control the licensing power were set aside and one of the most potent incentives to medical politics and intrigue was swept away. The rational principle was established that it is the duty of the State to assume complete control of the safeguarding of the health of the people. The principle was formulated by Commissioner Draper that the State may properly establish and uphold a single scientific basis for the practice of medicine in all schools. "Establish a fundamental standard for all medical practice," he said, "which will protect the people against ignorance and let those who can come up to that standard practice."

The law of 1880, to which reference has already been made, contained another feature of the greatest importance, that of requiring all persons engaged in medical practice to register their licenses in the office of the County Clerk. The significance of such a requirement is obvious, for an authentic license must be presented for registration. Any practitioner whose name does not thus appear is an illegal practitioner and is at any moment liable to arrest and prosecution. This list is consulted almost daily by the legal department of this society and much of our legal work would be impossible without it. This law uncovered a surprising number of practitioners who were not graduates from any medical school. I was cognizant of a man who had long done a considerable practice upon a sutler's certificate which he had gained during the Civil War. He came to New York and took a course in Bellevue College, and obtained a legal license.

Preliminary education of medical students has been another important subject of State legislation, the law of 1889 being the first radical enactment. Previous to that time there was virtually no State requirement as to preliminary education, and scores of students came to the medical college direct from the country district school. Advances in preliminary requirements have been made from time to time until now twelve years of preliminary education are required by the statutes of this State, namely, four years in the primary school, four years in the intermediate school, and four years in the high school. This subject of preliminary education is probably being now discussed more earnestly than any other pertaining to medical education and licensure, and views are very divergent. The medical colleges of this State are finding that the students from the average high school have not a satisfactory basis upon which to begin the professional training required for a modern physician. This is true even of the high schools of New York, which are the best in the country. In many of them instruction in chemistry and physics is inadequate and the feeling is strong among the colleges that more preliminary training is required. The remedies suggested are numerous. It is proposed by some to require a special preliminary course of one or two years. Others would require a five years' course in the medical college of those who have had insufficient training in physics and the biological sciences. This would virtually mean a year of preliminary study given in the medical college itself. Those who have had adequate instruction would be admitted to advance standing and could complete their medical course in four years. This plan has much to commend it.

Still others would require the first two years of the literary college course. This, it is true, would give a certain degree of intellectual culture, but it seems to me doubtful whether a medical college should make anything but knowledge of medicine an indispensable condition for the granting of a degree. I fully believe that the State has no right to set up any standard but that of knowledge. The question of intellectual culture as given by the literary college should be decided by the inclination and financial ability of the individual. The first two years in the curriculum of most colleges may give culture but it does not give the technical knowledge required by the medical student. The requirements for admission to the medical school should be

like those imposed by any other school, namely, the knowledge possessed by the applicant, not mere length of time spent in study. For the medical school, culture should be encouraged, technical knowledge only should be obligatory.

A few universities have perfected a plan for so combining the medical and literary courses that they may be completed in six or seven years. After three years in the literary college and one year in the medical college the bachelor's degree is conferred in recognition of the four years' work then accomplished. This scheme presents certain objectionable features, which will probably prevent its adoption except in universities having a medical department. A few medical colleges now require a full literary course of four years as preliminary to admission. Last year 15.6 per cent. of the medical students of the United States and 20 per cent. of those in New York were graduates of literary colleges. While it is right perhaps for certain colleges to adopt this severe requirement, very few advocate the proposition that the State should decree that only college graduates should be permitted to study medicine within its borders.

The advocates of radical increase in the preliminary requirements in the advanced states apparently do not consider the different classes of students who are being educated in the medical colleges of this country. They are of three general types. (1) A few will do little or no medical practice but will enter upon research work in laboratories and institutes and will devote themselves to the advancement of pure medical science. (2) A somewhat larger number will settle in the cities and adopt a specialty and in time will become consultants. (3) By far the greater number will scatter over the land, in both city and country, as general practitioners. The popular idea that most physicians are now specialists is without foundation. The family physician and general practitioner was never more firmly established in our social system than he is to-day. The first two of these classes will of their own volition seek the most ample training they can secure, that they may be the better able in later life to attain the high places in the profession. No legal enactment is necessary to induce them to take the higher education, either before or after graduation. To hurriedly raise the barrier too high against the third class would exclude many desirable men from the profession and bring about several unfortunate conditions. It would galvanize into new life many systems of quackery and weak third-class colleges. The great bulk of the medical students of the country are to become practitioners, not research workers, a fact ignored by some recent enthusiasts, and they should receive the training which will make them practitioners. Research and the specialties are subjects for postgraduate study.

Opinions differ radically and honestly upon this subject and I can only express my own. I cannot too strongly assert belief that every medical student who can possibly do so, should take a college course before he enters the medical school and a hospital course after graduation. I firmly believe that more preliminary education is desirable than is given by the average high school. But it seems to me that the time is not ripe for the general legal requirement by this State of more than one year of special preparatory work. This would involve seventeen years of unbroken study to obtain the doctor's degree in medicine. College-bred men who have spent twenty-two expensive years in preparation will not settle down in the villages and rural communities, unless they gravitate there after failure in larger places. They will seek return for their heavy investment, either in income or reputation, which they can best secure in the cities. Too rapid advancement of the medical standard will aggravate the present marked tendency to congestion of the profession in the cities and its depletion in the country. It would be unfortunate to fit doctors only for the easier and more attractive practice of the cities. Every raising of the educational bars adds incentive to the systems of pseudo-medicine to fight for a lower standard or to break in through loop holes. We had better hold what we have than to risk losses by premature attempts to advance our standards. It seems to me that the most we should ask in this State is one year between the high school and the medical college of those who do not hold a literary degree or have had no special training in the physical sciences, and at present I do not believe we should ask that.

Still another subject of State legislation has been that of the medical college course and the scope of medical education. The almost universal standard throughout the United States for many years was three years' study of medicine, with two courses in a medical college. The actual time of instruction in the medical college was often not more than five months in each year and the course was not graded. The remaining time was supposed to be spent in the office of a practitioner. When conscientiously carried out according to its intent, this system had much to commend it. The medical aspirants who were brought into close contact with practitioners of strong character and broad experience learned much of human nature and the humanitarian side of their character was early developed. They obtained a valuable fund of practical knowledge and acquired an attitude of mind toward the sick and unfortunate which scientific training alone does not impart. They were imbued with a correct professional spirit and obtained an esteem for the profession which the students of to-day do not always acquire. But there were many weak places in the system and they gradually became more pronounced. The average preceptor did not take the interest in his students that was taken by the doctor of fifty years before. As pharmacy developed and the office work of the medical student was reduced, the relations between preceptor and student became less intimate and instruction was frequently perfunctory and valueless. In too many cases the two short college terms furnished all the instruction in medicine which the student ever received. With these conditions coupled with the rapid strides of medical science, a different system became imperative. The whole system of instruction by preceptors was, therefore, wiped out when the State required three years' attendance at the medical college. In 1896 four college courses were required of at least seven months each in four different calendar years.

When the State assumed control over licensure under the law of 1890, three examining boards were appointed, representing the regular profession, the homeopaths, and the eclectics. Those boards began their work in 1891. It was not possible at that time to ignore sects in medicine. Although a compromise, it was a distinct advance. In process of time, however, systems of pseudo-medicine arose, and alleging that they were "schools" of medicine, demanded recognition. Without exception they asked for the privilege of practising upon educational re-

quirements inferior to those imposed upon physicians. Contest before the legislature was renewed year after year, for medical men necessarily combatted such demands. The profession chafed under the false position in which it was placed every winter by these contestants and the Legislature and the State Education Department became thoroughly wearied of them. Two courses and only two were open. The one was to recognize every medical sect as it arose and obtained a following and to give it a State examining board. The alternative was that the State should refuse longer to recognize medical sects, or "schools" of practice. It was impossible to longer maintain the three examining boards without adding to their number. The State Educational Department, therefore, took the matter in hand, upon the ground that medical laws are a part of the educational laws of the State. These laws are wide in their application, and cover many professions and diverse conditions, and are administered in all their ramifications by the State Education Department, an organization of great power and efficiency. "The first Assistant Commissioner is in charge of universities, colleges, and professional schools, and of the execution of the laws concerning the professions."

After long deliberation the Department laid down the principle that the State of New York, which does not recognize sects in religion, ought not to take cognizance of disputed dogmas in medicine and should not, therefore, put its seal of approval upon any medical sect or special system of practice; that it should establish definite educational requirements; that any person fulfilling these requirements should be recognized as a physician and should be licensed to practise medicine, using his own educated judgment in the selection of treatment. It was recognized that diagnosis is the foundation stone of medicine, as there can be no rational treatment without diagnosis. It was, therefore, held that every applicant to practise should be obliged to give evidence of sufficient education to diagnose disease.

This is the identical ground which I took in my inaugural address as President of this Society in 1905, when I said: "Our opposition to pseudo-medicine is and should be, educational, not professional * * *. The medical profession approves the system which requires the same education for all practitioners. We are not the ones who are seeking to bring half-educated practitioners through the back door. We simply ask equal requirements for all * * *. It is one of our fundamental principles that every man and woman exhibiting proper qualifications should be admitted to practice."

After much consultation the Education Department prepared a bill in which these principles were embodied and after a bitter struggle it was enacted into law in April, 1907. It was commonly known as the "medical unity law" or "single board law" but was in fact a general medical law, the most comprehensive that has been enacted since 1806. It did not emanate from the doctors but from the State Education Department, as part of a broad educational plan. Unless misled into unwise legislation, the State in the future will not again place its seal either of approval or condemnation upon any medical sect or ism. It is now on the sane and unassailable ground of licensing physicians as it licenses lawyers, dentists, pharmacists, veterinarians, nurses, and public accountants, without qualifying adjectives or restrictions as to methods of practice. Licenses are granted by the Regents upon the recommendation of a single examining board, nominated and appointed by the Regents and consisting of nine members. Examinations are conducted in anatomy, physiology, chemistry, pathology, bacteriology, hygiene, sanitation, obstetrics, gynecology, diagnosis, and surgery. The various specialties are included under the last two headings. The examinations are held simultaneously four times a year in New York, Albany, Syracuse, and Buffalo. About 750 candidates are examined each year.

It is sometimes asserted, and with truth, that examinations are not unmistakable means of determining fitness for practice. It would be difficult to devise any method that is strictly unmistakable. It should be understood that written examination is not the only test relied upon in New York and in twenty-six other States, for candidates are not admitted who have graduated from colleges of low standing. There are many colleges in the United States as well as in foreign countries whose graduates are not permitted to enter the examinations. Admittance is a guarantee that the applicant has had good educational opportunities. The examinations determine how well he has utilized them. It is no small thing that applicants from foreign countries must pass an examination written in the English language. A prime object of the State is to secure adequate education of its medical practitioners with the least possible interference with the colleges in their actual work. This object is admirably attained under this system, for in its supervisory capacity the State now has in its hands a potent means of keeping the colleges up to their work. The position of medical examiner is one of importance and responsibility. A competent and conscientious man may do much to cause the colleges of his State to raise the standard of education in his department. On the other hand, an examiner who lags behind the times or allows himself to ride hobbies may seriously impair that standard in his department.

Under our form of government the power to establish educational standards is vested wholly in the States. The standards, therefore, differ in each State and many unfortunate and actually unjust situations arise. This, however, is inevitable, for it is impossible for the general government to establish educational requirements, except for the army, navy, and marine hospital service. Upon elder practitioners who wish to remove to other States, this often inflicts great hardship. It is evident that a State with a high medical standard cannot admit practitioners from a State with a low standard without some assurance of fitness. It would be unfair to thus discriminate against its own students, who cannot escape any of the requirements, including an examination before a State board, and such discrimination is forbidden by the laws of New York. The blame for irksome requirements is usually placed by a disappointed candidate in the wrong place. When "reciprocity" between two States is not possible, the blame rests upon the State which permits inferior qualifications in its practitioners, not upon the one which has established a proper standard and takes the necessary measures to maintain it. The standard is still deplorably low in some States, there being no less than thirteen which have no legal requirement whatever for preliminary education. It is probable that in time a common standard may be evolved which will be acceptable in its essential features to most if not all the States. It is not possible

to force such a standard upon any State, and capable practitioners in low standard States must suffer whether they remain in their own State or remove from it.

Previous to 1907, certain osteopaths had been practising in this State under alleged shelter of the celebrated decision of Judge Daniels, which asserted that the administration of drugs was necessary to bring a practitioner under purview of the medical practice laws. In other words, until three years ago the practice of medicine in New York, according to judicial decision, consisted only in the prescribing of drugs. The opinion was forcibly expressed by many members of the State Senate that the osteopaths were here by tacit consent and could not then be legally evicted from practice, and they asserted that an adjustment of the rights of the osteopaths was necessary. Those holding this view formed a majority of the Senate and had passed a full osteopathic bill the previous year. Therefore, those osteopaths who were graduates from a recognized osteopathic college, and were already established in the State, if they fulfilled certain requirements of the Regents, were licensed by the law of 1907 to practise osteopathy, but were specifically forbidden "to administer drugs or to perform surgery with instruments." This was necessary to prevent State recognition and a full osteopathic examining board, which the Legislature would otherwise have certainly given, and it prevented the granting of greater privileges.

After November, 1907, a three-years' course was required of osteopaths and the same examination before the State board as that exacted of physicians. After 1910 an approved four-years' course and the State examination is required, thus placing all applicants for practising the healing art in New York upon the same basis.

Until 1907 there was no statutory definition in New York of what constituted the practice of medicine. The extraordinary decision of Judge Daniels, of the Supreme Court, has already been referred to. A judicial decision has the power of law in all lower courts. The importance of a proper legal definition in attempts to enforce medical practice laws is at once apparent. As a result of the persistent efforts of Mr. Champe S. Andrews, the recent legal adviser of this Society, other judicial decisions of very different character had been obtained. Using these as a basis, the following definition was written into the law of 1907 and was by no means the least of its important features: "A person practises medicine within the meaning of this act, except as hereinafter stated, who holds himself out as being able to diagnose, treat, operate, or prescribe for any human disease, pain, injury, deformity, or physical condition, and who shall either offer or undertake, by any means or method, to diagnose, treat, operate, or prescribe for any human disease, pain, injury, deformity, or physical condition."

The masculine pronoun has been used throughout this article without the intention of ignoring the admirable women of the profession. Their actual number is not large. In the United States last year but 3.7 per cent. of medical graduates were women. A portion of them will take up research work in laboratories and institutes and a considerable number will seek positions in sanatoria and similar institutions, so that the proportion of women in private practice is very small.

Some of the laws placed upon the statute books during the past 150 years have been enacted to meet changed conditions. A few have been retrograde in their effects and have lowered existing standards. The greater proportion, however, have been well-considered steps toward better conditions. Laws of this character have been enacted during every decade since 1792, except during the sixth and seventh decades of the last century. During that time the homeopathic and eclectic medical societies were chartered and invested with legal powers. From 1854 to 1872 not a single law to advance the standards of medical education or practice was enacted. This is a striking commentary upon the folly of professional strife and contention. During the time when the contest between the schools of medicine was at its height, the energies of the profession seem to have been completely exhausted by the strife. Not a single successful effort was made for eighteen years to improve professional conditions by new enactments.

Since 1872 legislative enactments have been frequent and important. Without exception the object of successful efforts has been to equip medical men more thoroughly and to render medical practice more effective. Compromises have sometimes been accepted, but the effort has been persistent and tireless to make at least a little advance in each new law. As the profession has become more homogeneous, its influence has vastly increased and has been steadfastly used to further every effort to send out better qualified physicians to the people. A united and homogeneous profession will, without doubt, be able to hold all that has been secured. If judicious it will in time be able to attain its ideal standards for both education and practice.

The laws of New York as they now exist are but a reflection of a tendency that has been active for fully three decades. They recognize physicians only and take no cognizance of medical sects. The profession itself has been rapidly drifting to the same position and is now more homogeneous than it has been at any previous time for almost a century. It is a surprise to most physicians as well as to laymen to know how little the profession of to-day is divided into "schools." Few medical practitioners are now willing to place upon themselves either legal or moral bonds to limit their practice to a single method. They wish to be free to adopt every resource in diagnosis and treatment which modern science has placed at their disposal and refuse to be restricted by a dogma.

Of the 22,145 students in the medical colleges of the United States last year, 20,554 were in the regular colleges. Of the graduates of the New York State medical colleges, 93.2 per cent. were from the regular colleges; 4.8 per cent. from the homeopathic; 2 per cent. from the eclectic. In the United States, 92.1 per cent. of the medical graduates were from the regular colleges, the remaining 7.9 per cent. being divided between the homeopathic, eclectic, physiomedical, and nondescript colleges. In other words, 92 of every 100 medical graduates prefer to go out to their life work without sectarian limitations and restrictions, bearing only the simple and honorable title of physician.

113 West Ninety-fifth Street.

Pediatrics and Orthopedic Surgery.—Steinhart calls attention to the necessity of the study of these branches of medicine as they should be. It is disconcerting to see men who are wholly ignorant about these specialties treating or pretending to cure cases that fall to the lot of the specialist.—*Crónica Médico-Quirurgica de la Habana.*

IS INSANITY INCREASING?

By AMOS J. GIVENS, M. D.,

STAMFORD, CONN.

We may point with pride to the record of progress in the arts and sciences, and especially in the humanities and philanthropies of the nineteenth century. We may rejoice that we were privileged to form a part of that great army of workers who in its closing years gave a new impetus to the many movements for the betterment of State and nation. The nineteenth century made immense strides in advance of any of its predecessors, but its record is no less admonitory and instructive than it is stimulating, for it is ended. It may not now, though we wish it ever so much, be altered or revised. It is irrevocably closed. To that gift, however, which it held by inheritance, the most valuable of all its possessions—the gift of opportunity—the twentieth century has fallen heir. It is the recognition of the value of this gift, and of the highest use to which it may be put, that is the fundamental cause of the existence of the body of altruistic men and women gathered here to-day.

This Conference of Charities, the first ever held in the State of Connecticut, is a notable event in the history of a commonwealth ever distinguished by its enlightened and progressive spirit. The occasion calls together from various sections of the State men and women deeply interested in the welfare of feeble-minded and defective children; men and women who have devoted their lives to the betterment of individuals who are in the industrial schools, reformatories, jails or prisons, as well as those who need the special treatment and protective care of a State hospital or sanitarium. In fact, this conference is composed of persons who are actively interested in sick and suffering humanity. It enables those who are co-workers for the betterment of the sick and unfortunate to meet, to exchange helpful ideas, and to combine all of the agencies in the State having a part in this beneficent work.

The subjects which necessarily demand your consideration are very many. When they are regarded attentively, it will be seen that each requires not only a knowledge of past and present conditions in the State or country, but also a comparative knowledge of conditions in other States and countries. To this must be added a comprehension of underlying causes, so that the trend and outcome may be intelligently recognized and forecasted, and remedial measures wisely chosen.

One of the most important of these topics is undoubtedly that which I have the honor to bring to your attention to-day, and that is, "Is Insanity Increasing?"

And first, in a country like the United States, of such a cosmopolitan people, it is necessary to know whether, relatively to the proportion each bears to the total population, the native born or the foreign born furnishes the larger number of the insane. the answer is, the foreign born. That is to say, government statistics tell us that of white individuals at least ten years of age in the general population of the United Sates in 1900, 80.5 per cent. were native born and 19.5 per cent. were foreign born, while of the white insane of known nativity enumerated in hospitals, 65.7 per cent. were native and 34.3 per cent. were foreign born! To a nation receiving a million of immigrants a year, such a fact is of great significance.

Aliens come to us chiefly by way of our seaports, and it is therefore pertinent to inquire what protection we are receiving at these points of entry. About two years ago, in accordance with the suggestion and advice of Theodore Roosevelt, a special commission was organized for the purpose of investigating conditions in Europe, and for lessening, if possible, the number of insane or defective persons constantly seeking homes in the United States. During a period covering one year, and the last year of which we have any definite report, there were admitted at Ellis Island, New York City, 424 insane persons. The immigration inspectors succeeded in deporting all of this number. Forty-nine insane persons were sent back to Austria, 37 to Germany, 28 to Hungary, 74 to Italy, 76 to Russia, 12 to Sweden, and a small number to Turkey, Syria, Poland, Norway, France, Denmark, and other European countries. It is of interest to note in this connection the number of insane refused entry at Ellis Island in 1907. This number was 189, to which must be added 360 deported for insanity the same year. Of the 360 there were 64 Irish, 43 Greeks, 35 Northern Italians, and 32 Scandinavians.

The immigration laws are now very strict, but have been rigorous for only a short period of time, and for many, many years defective and unbalanced aliens have not only sought homes in this country, but perhaps have been intentionally sent here. By referring to the statistics of the foreign born population of our insane hospitals, it will be observed that it will take a long time for a lessening of these conditions and a demonstrable change for the better; but with a commission like the one established by Congress, and with the rigid laws for the exclusion of defectives, it is reasonable to suppose that eventually this evil will be somewhat abated. Should the phrase "somewhat abated" suggest but a moderate degree of optimism, let it be remembered that many factors enter into the problem for which even deportation of immigrants becoming insane within a stated time after admission cannot wholly provide.

The annual report of the Commissioner-General of Immigration for the year ending June 30, 1907, contains this interesting statement: "The vast majority of the arriving aliens have been destined to a few of the large cities, over 30 per cent. to New York State." Now, on October 1, 1908, there were 30,507 patients in the various hospitals for the insane and sanatoria in New York, an increase of 1,414 over the previous year. Concentration of population, and consequent and ultimate degeneration mentally in those unable to withstand the change to such environment, exclusion and deportation cannot adequately provide against.

The first census of the United States, in 1790, gave only eight cities of eight thousand or more inhabitants and containing 3.4 per cent. of the total population. In 1900, on the other hand, there were 545 such cities, holding 33.1 per cent. of the total population, while of this total number nearly 26 per cent. was distributed in communities of 25,000 or over. Urban life provides not only a highly stimulating environment, but one in hygiene and housing least favorable to the integrity of the nervous system. Above all else, urban life offers every facility for the indulging in those vices, extravagancies, and breathless pursuit of fortune and pleasure increasingly hostile to normal mentality or the begetting of normal offspring. These factors affect native as well as foreign born individuals, but not equally. To a certain extent the former are, as it were, con-

genitally acclimatized to this artificial atmosphere; the latter are not.

Again, not only is there a yearly increase in the number of the insane in New York State, but also an increase in excess of the growth of the population. This increase during the past twenty years has reached 97 per cent., while the population has increased in the same time only 53 per cent. The ratio of insane to the general population in the State of New York, according to the latest figures, is 1 to 340. Figures from other States taken at random tell the same story of constant increase. Idaho, for instance, gives us such reliable figures as these: Insane patients under State charge, proportion to population in 1880, about 1 in 1,300; in 1900, 1 in 769. For the State of Washington in 1880, 1 in 695; in 1900, 1 in 402. Dr. Fletcher, of the State of Indiana, says that fifty or a hundred years ago it was rare to hear of a case of lunacy; now it is of almost daily occurrence. To-day in Indiana there is one case of insanity in every 400 of the population. About the same ratio obtains for Illinois. In Virginia the ratio of insane to the general population is 1 in 540.

We should naturally expect that in those communities where the stress and strain on the nervous system is greatest, degeneracy would be most evident. This is increasingly being demonstrated, as has already been pointed out, urban life proving a hot bed of degeneracy, and insanity one of its most prominent forms. It is possible that there is a certain fallacy in these figures of the increase of insanity, but not enough, it may be confidently assumed, to vitiate them to any extent. The better and more reliable the statistics, the less liable are they to underestimate the proportion, and it is highly probable that their accuracy has been increasing with each decade. Any error, in any case, would be in favor of a better proportion, and of fewer insane.

The attitude of the scientist must ever be impartial and dispassionate; the discovery of truth, and not the confirmation of his impressions or prejudices, is primarily his object. It is proper, therefore, to point out such elements in the present inquiry as might lessen the significance of statistics quoted. Such elements are chiefly increased longevity of the insane, with consequent decrease of mortality, attributable to the marked improvement in the care and treatment of this class of cases, but adding as a result to the number of uncured cases. There should also be cited the greater tendency at the present day to transfer the insane to the protection of hospitals and sanatoria, rather than to endeavor to provide for them in their homes.

Undoubtedly in the compiling of statistics the maximum of accuracy as to the actual increase can be obtained only by reporting the number of new cases occurring each year. While this would probably give us somewhat better figures, it is unfortunately highly improbable that the most conservative returns would indicate other than a steady increase. This increase, varying in degree, its exact ratio for the most part not yet determined, has been noted in nearly every civilized country where registration of the insane exists.

It would be impossible within the limits of a single paper to survey in the most cursory way the situation in all these countries. Conditions in Great Britain, however, may be cited as fairly illustrative, and of peculiar interest since the English speaking nations are so closely allied.

In Great Britain the figures of the English commissioners in lunacy show that in 1860, 1 in every 523 of the population was insane; in 1870, 1 in 411; in 1880, 1 in 360, and in 1890 the ratio had risen to 1 in 320. In thirty years insanity had therefore increased from 1 in 523 to 1 in 320, or had come unpleasantly near to doubling the ratio to population in that period. For England and Wales the commissioners in lunacy gave out the statement that January 1, 1903, the proportion of insane to population was 1 in 293. For the previous year it was estimated that the number of people throughout England and Wales who lost their minds was 22,581, or about 500 per week. This is about 3 every hour, day and night. January 1, 1904, the ratio had increased to 1 in every 285 of the entire population of England and Wales. Dr. Robert Jones, in his presidential address on the "Evolution of Insanity," delivered before the Medico-Psychological Association of Great Britain and Ireland, July 26, 1906, after quoting the above figures, said: "We also know that possibly the same number are on the borderland of insanity and are being daily precipitated into the asylums."

For Scotland in 1907, it was reported in the London *Lancet* that during the last three years there had been a decrease of insane persons in proportion to the population, and that this was the first time such a thing had occurred since 1858. During the whole period, however, the increase had amounted to 200 per cent., while the population had increased only 56 per cent. While this tremendous increase was attributed in part to the large number of senile cases no longer cared for in their homes, as well as to a remarkable increase of senile insanity and of general paralytics, the temporary decrease for the last three years of the number of the insane registered in asylums had been attributed in part to a growing disinclination among the upper classes to send the mentally diseased to public institutions. We find that this attitude is also common to the upper classes in England, and is yearly becoming more evident, and just the reverse of conditions with us. In Ireland, between 1871 and 1901, there was no appreciable increase in the proportion of insane to population between the ages of 20 and 55, but there was a very large increase in ratio in the old-age period. The situation in Great Britain, then, as a whole, is one showing a steady yearly addition to the number of the insane. Into causes we cannot go to any extent. The causes operative in Britain are operative here, and will be briefly enumerated later.

In all data relating to the United States, you will have noticed there was no reference to our own State, on the principle that that which is of greatest interest to us may fittingly be reserved until the last.

In Connecticut, the increase in insanity has not been so great as in a State with a seaport like that of greater New York, a State with a population of which approximately 30 per cent. is either foreign born or of foreign parentage, and 60 per cent. of its insane, also, either foreign born or of foreign parentage. But that there is a steady if relatively small increase in the number of the insane in our own State, we cannot doubt. The figures for the total number of insane persons under restraint in 1904 were 3,120; 1906, 3,351; 1908, 3,603. With a population for the State in 1900 of 908,000, the ratio of insane persons under restraint

was 3.2 per thousand. With an estimated population for the State in 1906 of 1,000,000, the ratio of insane persons under restraint at that time was 3.3 per thousand of the population. In 1908, estimating the population at 1,025,000 the ratio rose to 3.5 per thousand, a very decided gain for so short a period.

From the reports of the State hospitals of Connecticut, we learn that the annual average increase for the twenty years preceding 1900 was 76; during the next two years it rose to 90; while in 1907 the number reached 134, the same number being maintained for 1908. We should be misled by these figures, however, did we not make due allowance for the accumulation of insane in hospitals and the commitment to them of cases formerly cared for elsewhere.

In times gone by it was customary to provide for imbeciles, idiots, epileptics, old people or dotards, or persons evidencing the physiological decay of senility, as well as persons suffering from alcoholic insanity, in the individual's home or that of friends, oftentimes a portion of the house being set aside and arranged for their custody and welfare. This is hardly to be wondered at when the methods of the past, as to the public disposition of the insane, are contrasted with those of the present. The institutions of those days known as insane asylums have undergone so material a change as to be hardly recognizable in the State hospitals of the present. Restraint, the chief and almost the only idea in the past, has been so modified and improved upon by modern conceptions of the nature of insanity, and the possibilities of prevention and cure—to say nothing of humaner methods in the management of the insane while protecting society—that the great public at large is fast coming to realize that to be able to place the mentally afflicted in the care of physicians of great experience and skill, under the most favorable conditions for improvement or recovery, is an opportunity not to be lightly foregone. The result is that persons who were formerly cared for in their own homes are now cared for by the State. The hospital life is systematic and methodical, the hours and meals regular, the diet nutritious and carefully selected, various healthful activities encouraged, entertainments often provided, and hygienic surroundings secured so far as the frequent overcrowding of these hospitals makes it possible.

It has been said that during the past twenty-five years there has been such a revolution in public sentiment toward general hospitals for the sick that the average individual seeks, or willingly would seek, hospital treatment for any condition, from that of an attack of grippe to one requiring surgical intervention of the highest order. The same revolution is now taking place in the attitude of the public to hospital treatment for the insane. Both economy in administration and efficiency in treatment are thus largely promoted, and whether to the general advantage of society or not, the lives of the insane are prolonged.

The causes of insanity furnish a most interesting and fruitful field for investigation, and their bearing upon the increase of insanity becomes the more obvious the more they are studied. They are, therefore, essentially pertinent to the subject of this paper, although their mere enumeration will be sufficient to show that any extended consideration is impossible at this time. Hereditary predisposition, alcoholic excess, and influenzal poisoning have recently been assigned by a London alienist as the three principal causes of insanity in Great Britain. To syphilis in conjunction with the free use of alcohol, he attributes 70 to 80 per cent. of the cases of general paralysis coming under his observation. Another English alienist says: "If only the evils of alcohol and venereal diseases were disposed of, then half the problem of insanity would disappear with them." Additional causes are found both in our own and other countries in sudden changes in environment, trauma, fevers, and infective processes, the excessive use of drugs, especially morphine and cocaine, sexual excesses and perversions, overwork, malnutrition, the suppression of normal functioning of the generative system, conditions incident to puberty and the menopause, to pregnancy, and more especially to the puerperium. Much emphasis must be laid upon emotional factors, heightened and multiplied by the concentration of population, with the numerous stresses incident to progressive civilization and its limitless demands upon the highest organized structures of the human body.

To heredity, 60 to 70 per cent. of cases of insanity are attributed, while alcoholism is given the second place. Yet we find the statement, so far uncontroverted, that 50 per cent. of the inmates of all the insane hospitals in the United States are descended from alcoholic parents. A study of 520 males, new admissions to the Norristown State Hospital for the Insane, Norristown, Pa., from April 1, 1907, to April 1, 1909, gave the following results: "In 46 per cent. alcohol, either alone or in combination, was an important etiological factor. In 13.5 per cent. they were classed as alcoholic psychoses. In 41 per cent. of the imbeciles and 34.5 per cent. of the epileptics, alcohol was responsible for their commitment."

In the course of this statistical study of alcoholism as a causative factor in insanity, the percentages for male patients whose psychoses were due to alcohol are quoted as follows: "In the State of New York, 28.9 per cent.; Massachusetts, 30.6 per cent.; in a group of three asylums in England, 26.3 per cent.; in a group of five asylums in Austria, 24.9 per cent. Of 961 cases of insanity in the Manhattan State Hospital, New York, in which the causation was accurately determined, it was found that alcohol alone was the cause of mental impairment in over 40 per cent. of the men, and more than 25 per cent. of the women. Over 33 per cent. of insanity, epilepsy, idiocy, and prostitution," says Dr. Kraeplin, "shows alcoholism in parents." Statistics indicate that out of 22,113 cases of insanity admitted to the public institutions of France, 2,896, or a little more than 13 per cent., were directly traced to alcoholism. By referring to the report of the Connecticut Hospital for the Insane of 1908, we find a table enumerating the causes of insanity in 12,823 persons admitted since the opening of the State hospital. Intemperance is given as the cause of insanity in 1,566 cases. These figures represent more than twice the number of cases of insanity due to any other two of the known causes.

It is now a well-established fact that the excessive use of alcoholic beverages may induce nearly every form of insanity from simple sensorial aberrations to general paralysis. Indeed the rapid increase of the latter malady here and abroad is attributed almost entirely to intemperance. If, as is the case, the toxic action of alcohol is manifested even when

taken in comparatively small quantities, not only by outward signs but also by marked changes in the cortical neurons of the brain—changes in the cells of the brain which are clearly demonstrable—its long continued and excessive use must produce the most disastrous and ineradicable results. These cells are the media of the expression of the highest consciousness of man, and it is the law of his physical being that these most highly organized tissues should sustain the most irreparable injury, and that the influence of degenerative changes, physical, mental, and moral should be impressed upon his descendants.

For years different statutes have been enacted in various states for the purpose of regulating the liquor traffic. The manufacturers, distillers, and brewers expend $355,000,000 per year for raw materials for the manufacture of these beverages. The United States Government, from 1863 to 1907, has collected liquor taxes and duties amounting to $3,540,011,893. In 1880, 10 gallons of liquor of all kinds were consumed per capita in the United States; in 1890, 15½ gallons per capita; in 1900, 17½ gallons per capita; in 1902, 19½ gallons per capita.

According to a map of the United States pubished in November, 1909, to show the advance in temperance reform, Pennsylvania, Wyoming, Idaho, Utah, Nevada, and Arizona are the only states without at least partial prohibition, yet we find the statement that, in the last twelve years, the manufacture, sale and use of liquors have doubled. Prohibitory laws do not necessarily lessen the sale of stimulants or their consumption, but do change the situation to the extent of causing a substitution of closed doors for open doors. Prohibitory laws are seldom enforced, but apparently favor the multiplication of kitchen bar rooms, with inferior liquors and the most demoralizing surroundings. High license and restricting the number of licenses do not materially lessen the consumption of ardent spirits, nor will any number of license fees at $500 or $1,000 each ever reimburse taxpayers for the enormous expense of caring for the insane, the criminal, the pauper, and other classes recruited so largely from the ranks of the victims of the liquor habit. The best preventive measure, and the best solution of the problem, would be not to manufacture or import any alcoholic beverages at all. Such a solution being wholly and entirely out of the question, some practical measure must be adopted.

Within the past few years the attention of the public has been called to the danger of consuming impure food. Such a danger exists as well in respect to beverages, especially those containing alcohol. We have in this country a pure food law passed by Congress, intended to regulate the purity and adulteration of foods, but it either does not apply to liquors or is not effectively enforced with regard to them. In some European countries laws have been enacted, and are enforced, which inflict severe penalties for the adulteration of wines, and if in this country we must have liquors, we should be equally protected not only against adulteration but also against the use of liquors of an inferior grade.

Apparently the most practical measure yet advocated, is one which proposes both to lessen the sale of liquors and to eliminate their most harmful elements through the passage of a law by Congress, forbidding the collection of taxes on liquors until ten years after their manufacture, they to remain in bond during this time. Imported liquors would be required to be accompanied by certificates that they were made ten years before being shipped. The sale of beers would be restricted to those having been made more than six months. This plan is based upon the fact, doubtless well known to you, that liquors are more injurious when recently distilled or brewed. The cheaper grades of strong liquors contain an excess of fusel oil including various other poisonous constituents such as aldehyde alcohol, butylic alcohol, amylic alcohol, and furfural. These are the liquors bought and sold in enormous quantities, their crudeness partially concealed by the addition of syrups and prune juice, but incapable of containing anything to modify at any age their deadly and toxic action upon man's vital organs, and especially his wonderfully sensitive nervous system. In high grade liquors, on the other hand, properly made, aged, and matured, the fusel oil is largely eliminated as such by chemical transformation into essential oils and ethers, while the time required for this process—from ten years upward—both reduces their volume and very materially increases their cost. The provision affecting the sale of beer would prevent the manufacture of low grade beers, also, as they would not keep for a period of six months. The uniformity of such a law, the consequent diminution in the supply of alcoholic beverages, and the increase in their cost should markedly reduce the number of those using alcoholic stimulants; while those indulging in them would no longer be exposed to the deleterious effects of injurious constituents. One of the greatest causes of insanity would thus be regulated and restricted.

This is an age of great enlightenment and rapid progress. We ourselves can bear witness to this. Wireless telegraphy is the marvel of the age, approached only by aerial navigation. New means of rapid transit or communication, or improvements in existing facilities are almost daily brought to our attention. Schools, colleges, laboratories, universities are multiplied. All the sciences are fostered, including the art and science of medicine. Moneyed men and women freely endow institutions for the investigation of the cause and cure of the most contagious or most baffling diseases, while medical science seems to be on the very verge of solving the most difficult problems they present.

The State of Connecticut, which has always been a leader in educational matters, is also abreast of the times in medical affairs, and in this connection its Legislature has appropriated a considerable sum of money for the construction of a special building, or a special section, as an adjunct to the State Hospital for the Insane, to be known as the psychopathic pavilion. The object is to encourage the early treatment of insanity, in order that incipient cases may have that immediate and skilled care and treatment most favorable to their prompt recovery. The statement has been made for both Europe and the United States that fully 50 per cent. of those recovering from insanity began treatment in the first three months of the disease. The necessity for their early care is thus emphasized forcibly.

During 1908 the average number of the insane under restraint in Connecticut was 3,603. For their custody, care, and treatment the State has made wise provision, and there are at the present time two State hospitals and twelve private sanitoria in which they are received.

The formation of a medical society in the State

of Connecticut, the Connecticut Society of Alienists, may be cited as still further indicative of the spirit of progress most fruitul in the betterment of the social body. This society was established about two years ago, and held its annual meeting in New Haven last January. It numbers among its members the superintendents and assistant physicians of various State hospitals and sanatoria, as well as eminent specialists throughout the East who are devoting their time to the treatment of insanity. It also has the cooperation of numerous persons who are interested in this scientific and important subject. The members, almost without exception, are in a position to devote considerable time to scientific research, and with the assistance of the numerous specialists elsewhere throughout the New England States, it is expected that a great deal will be accomplished in the study of the causes, care, and prevention of mental and nervous diseases. The object of the society is specifically stated and defined in the first article of the by-laws which reads as follows: "The purpose of the society shall be to promote the welfare of those afflicted with mental and nervous diseases in this State, to encourage the discussion and promulgation of scientific principles, and the adoption and application of the most approved methods for the care and restoration of those mentally or nervously unbalanced, whether in the incipient or more advanced stages."

When to the collective efforts of this society are added the work of the various hospitals and sanatoria, and the efficient aid received through the sympathy and cooperation of the Connecticut Conference of Charities and Correction, who can doubt that material service will be rendered the State, and that great progress will be made in this essential and beneficent undertaking. At the same time it should be remembered that one of the most important and helpful boards which the State has, and has now had for many years, is that known as "The State Board of Charities." It is composed, as you know, of five members who are appointed by the Governor and confirmed by the Senate. Its powers as defined by the State are comprehensive and far-reaching. It has the supervision of all the almshouses, homes for neglected or dependent children, hospitals for the insane, and all hospitals and other institutions for the care and support of the dependent and criminal classes. The members of this board have always generously given their time and services, and with the truest altruism have devoted themselves without reward to promoting the welfare of those for whom the State is responsible. A moderate sum of money has been appropriated in years gone by for the expenses of this board. But the amount certainly seems very inadequate for the carrying on of work so extensive, and resulting in so many and obvious benefits to society. It is greatly to be hoped that the good work this board has done and is doing, may be fully recognized and endorsed in the future by a reasonably increased appropriation.

In conclusion let me say that we can not be too generous in the acknowledgments we pay to the different agencies which, under the fostering care of our State, contribute to the protection and well-being of all citizens. We can not be too ready to join in encouraging their aims and efforts. We must mutually labor for the support and upbuilding of our institutions and societies for the care and cure of those afflicted in mind or morals, in body or estate. Not least among these are the afflicted in mind, and as we mark the increase in their number in this and other countries we shall, I believe, apply ourselves with renewed energy to securing those favorable conditions in public and private life, which shall tend to bring about more rational living, and a consequent lessening of insanity by decreasing the army of neurotics and the congenitally defective, from which the ranks of the insane are so largely recruited.

ANTIDOTE FOR ALUMINUM PHOSPHATE, THE POISON THAT CAUSES MILK-SICKNESS.

By E. L. MOSELEY,

SANDUSKY, OHIO.

In the MEDICAL RECORD of May 15, 1909, the writer showed that milk-sickness is due to aluminum phosphate. At that time he had never had an opportunity to examine milk or butter that had actually caused the death of persons. But the following September a family living on a farm in Sandusky County, Ohio, lost two children from milk-sickness caused by butter. They had very little milk on their table, as nearly all the milk that their two cows supplied was used for making butter. The cows were kept in a woodland pasture where the only other grazing animals were four horses, which were turned in the pasture at night. These horses were afflicted with trembles, though not fatally. In the woods the white snakeroot was well distributed, and, as has been found in so many other places where trembles have originated, a large part of the snakeroot had been browsed, the grass being poor. A crock of butter from which the family had been using before the disease was diagnosed was sent to me, and I found it to contain about two one-hundredths of one per cent. of aluminum phosphate. This determination has been verified in other laboratories.

The butter fed to kittens produced milk-sickness or trembles for a few days, but they would not take very much of it. A corresponding amount of aluminum phosphate put on fat meat was taken readily and caused the same symptoms. With lean meat it produced trembles, but the effect was not so pronounced as with fat meat. When given with a diet mainly vegetable (potato or pancake), it had no perceptible effect. With milk it was generally less effective than with fat meat, although a single dose of .03 gram of aluminum phosphate given in milk to a kitten weighing 1½ pounds was followed by trembles, resulting in death in seven days. Cats poisoned with aluminum phosphate shun fat. They prefer potato to meat, and in some instances they take potato in preference to milk.

A little soda generally prevents the aluminum phosphate from doing any harm. This was found true of the butter as well as the aluminum phosphate artificially prepared. Once potassium bicarbonate was tried instead of soda, with the same result. In some of the tests commercial baking soda was used, in others chemically pure sodium bicarbonate. Different amounts of soda were used, but .02 gram seemed to be enough for 25 grams of the butter. When a little aluminum phosphate and alkaline carbonate were given with a quantity of fat meat, the meal was not readily digested. The use of soda in milk-sickness was recommended by W. E. Walsh of Morris, Ill., who, having found diacetic acid in the urine of his patients, administered soda at intervals with good results. After the funerals of the children referred to above their father became quite sick with the same trouble. Following Dr. Walsh's example, soda was given, and he made a speedy recovery. Soda put in the feed of his horses was followed by noticeable improvement in their condition.

Aluminum is less basic than the metals normally present in the animal tissues. Its salts have an acid reaction. The serum of cats which had taken several doses of aluminum phosphate I found to have a lower titration alkalinity than that of normal cats. In one case the alkali in one gram of serum was equivalent to not more than .0002 gram of sodium carbonate; in others it was several times this amount, but less than in a normal cat. The urine of the cats that had taken the aluminum phosphate was strongly acid. Dr. Walsh writes me: "The acidosis, I believe, is the cause of the extreme symptomatology." We have reason to believe, therefore, that a part of the injury to the system produced by aluminum is due to its producing a tendency to acidity. Hence the usefulness of an alkaline carbonate. The pancakes referred to were from a restaurant and not intended for experiments, but soda had been used in making them. Potatoes contain considerable potassium. I presume that some of this potassium is in such form as to neutralize the aluminum. A neutral salt of an alkali metal does not answer the purpose, for the butter referred to contained much common salt.

Probably many kinds of vegetable food contain enough alkaline carbonate to neutralize the minute amounts of aluminum contained in the same foods, and even considerably larger amounts. Animal foods are relatively poor in alkalis. Persons taking with impunity considerable of the butter that has caused milk-sickness in others may escape from injury on account of their diet containing more alkali, but commonly it is because they eat less of the butter. The boy referred to is said to have eaten about half a pound of butter each day, and the girl was also very fond of it. Three men eating the same butter once a day for a week were unaffected, but a relative who remained with the family three days had some milk-sickness. A little of this butter, 3 grams, had no perceptible effect on a cat, nor 12 grams on three cats.

Do butter and fat meat with aluminum phosphate prove so effective because they contain less alkali than other foods, or because the digestion of fat withdraws so much alkali from the blood, or is it because the fat is a good vehicle for carrying the aluminum into the blood? The following explanation I am inclined to think more important than any of these. It is likely that the aluminum phosphate, dissolved by the hydrochloric acid of the gastric juice, is slowly absorbed, absorption continuing as long as the food with which it was mixed remains in the stomach, but ceasing when it mingles with the alkaline pancreatic juice. Fats, as shown by experiments of W. B. Cannon on cats, "remain for a long period in the stomach, and leave that organ slowly. Carbohydrates remain in the stomach about half as long as proteids." Thus the aluminum phosphate, if given with much fat, remains for a long time in an acid medium; if with carbohydrates, for but a short time. "When fat is added to either carbohydrates or proteids it retards the passage of both foodstuffs through the pylorus."

Several peculiarities of the disease may be due to the acidic tendency produced by aluminum. The serious consequences of prolonged or violent exercise observed in persons affected with milk-sickness and in various domestic animals affected with trembles may be due to the production of sarcolactic acid without enough sodium carbonate in the blood to neutralize it. Moreover, diminution in alkalinity is accompanied by a diminution in the capacity of the blood for carrying off carbon dioxide, whose production is increased by exercise. The accumulation of carbon dioxide explains the panting so noticeable in milk-sick animals after exertion.

Lambs and calves are very susceptible to milk-sickness, often dying from it without their mothers showing much effect of the poison. Unlike their mothers, they are subsisting on animal food, and so are not getting enough alkaline carbonates to neutralize the aluminum contained in the milk. Our analyses showed that the aluminum contained in one day's milk of a cow which had been taking daily ten ounces of white snakeroot was not a large fraction of the quantity of aluminum contained in the snakeroot she had eaten.

Dogs and cats get trembles by eating considerable of the meat of animals that have died of that disease, although the amount of aluminum phosphate contained in the meat they eat is much less than that contained in the food of the animal that died, but the latter was subsisting on a vegetable diet, and our experiments have shown that a very small amount of aluminum phosphate, when given with a vegetable diet, is not harmful, but with an animal diet it is.

The recurrence of milk-sickness after recovery from the first attack is doubtless due to the persistence in the tissues of the phosphate or some other compound of aluminum. Such recurrences are said to follow overwork and overeating. An eight-pound cat which at first was made quite sick by aluminum phosphate in time became accustomed to it so that the effect was less marked. After daily doses for two weeks of about .06 grams, with oc-

casionally larger amounts, he was chloroformed and some of the tissues examined for aluminum, with the following results, expressed in grams of aluminum phosphate found in the ash of each gram of tissue: Clotted blood, without serum, .00024; serum, .00020; small intestine, washed, .00008; liver, .00006; muscle from fore leg, .00006; fat, .00000; kidney, .00000; urine, .00000.

This animal had an enlarged liver. The urine contained neither albumin nor casts. In rabbits which died of trembles, albumin and casts were found in the urine, and aluminum phosphate in both urine and kidney.

The blood of cats that have been given aluminum phosphate appears to contain a fine white powder. In the blood of the cat mentioned above I observed this while the blood was flowing into a beaker from the vena cava ascending. On standing, this formed a scum on the serum. When poured on an ashless filter paper and washed, the filtrate contained no aluminum, but the paper with the residue was burned in a platinum dish and aluminum found. It appears, therefore, that an insoluble aluminum compound, probably the phosphate, occurs in the blood of these animals.

THE CARD SYSTEM FOR RECORDING HISTORIES OF PATIENTS IN PRIVATE PRACTICE.

By EBEN C. HILL, M.D.,
U. S. ARMY.

At the present time practically all of the leading hospitals in this country keep very accurate and complete records of their cases. The value of such a method needs no comment. Each patient is indexed and catalogued so that upon re-admittance a complete history with the previous diagnosis and treatment is immediately at hand for reference. The clerical work entailed, however, is considerable, and the general practitioner, although appreciating the value of these histories, finds little time for such complete records in his private cases.

Yet nearly every physician, at some time, has experienced a desire for a more detailed record of a case in which the diagnosis is obscure. Upon studying the symptoms he frequently finds that certain pertinent questions have been unasked, and that a few of the minor symptoms are hazy in his mind. As a result he must wait until these facts have been ascertained at his next visit before the diagnosis is settled and rational treatment begun.

For some time I memorized what I considered the more important questions relative to the habits of life and the symptoms which, although not bearing directly on the disease in question, were suggestive, and recorded the answers and observations. The clerical work involved and the time consumed made this method almost impracticable. After various other attempts at shorter methods, the following card system was devised and it has proved of value. The size of these cards (9.5 inches by 12 inches) is sufficiently large to allow considerable writing on the printed side, and yet can be folded so as to be conveniently placed in an inside pocket. Ordinarily, little writing is necessary except to note the dates at which illnesses have occurred and the results of the "Physical Examination" and "Present Illness." However, should more space be needed to complete the examination

or in detailing the treatment or subsequent diseases the reverse side gives ample space.

In the use of this system few details escape the physician, a ready reference is always at hand and a rather complete history is rapidly made. The absence of any of the listed symptoms or diseases is quickly noted by running a line though that disease or symptom. On the other hand, if any symptom or any fact in the family history has a very significant bearing on the case the importance of this is indicated by underscoring that symptom.

For instance, a history of tuberculosis might appear as in Card 2.

This system is, I believe, applicable to any of the branches of medicine. Each physician, surgeon or specialist has certain questions, symptoms and results of examinations to be recorded and all that would be necessary would be to formulate the cards so as to meet the requirements of that particular specialty.

The cost is comparatively small. Printed on medium heavy Bristol board of the size mentioned, the expense is about $8 per thousand. The size of the cards permits their being filed flat and arranged alphabetically or otherwise in practically any of the commercial sectional systems.

The noisy breathing of nasal obstruction, according to Pisek, should not be confused with true dyspnea. Particularly in infants are adenoids, enlarged tonsils, acute rhinitis, the snuffles of syphilis, congenital obstruction, and cretinism liable to give rise to this symptom.—*The Post Graduate.*

THE MANAGEMENT OF HEMORRHAGE DURING OPERATIONS ON THE TONSIL.

By CHARLES J. IMPERATORI, M.D.,

NEW YORK.

SURGEON, N. Y. THROAT, NOSE AND LUNG HOSPITAL.

As far as can be ascertained, there are few operators who pay any particular attention to the amount of blood lost during operative procedure on the tonsil before operation, during operation, or post-operative, unless there is considerable bleeding: most men considering it as one of the annoyances that must be encountered when operating in this region.

While it is true, as we all know, that the great majority of cases cease bleeding within a few moments after the operation, there are cases that during the operation give us considerable trouble, because of the hemorrhage-in obscuring the field, particularly during the complete removal of the tonsil. I might add, that, while it is certain that most cases are materially benefited by a tonsillotomy or a partial removal of the tonsil, it seems to me that, for the benefit of those few and infrequent cases of return after tonsillotomy, we should perfect our technique so that all of the diseased tissue will be removed. A tonsillotomy by means of the tonsillitome is comparatively an easy operation; the enucleation of the tonsil is somewhat more difficult. It is admitted that the past has shown good results in the majority and individual cases where tonsillotomies have been done. Occasionally we see chil-

dren with enlarged remains or stumps that appear to all intents as hypertrophied tonsils. The fact that the operator tries to get as much of the tonsil as possible with the tonsillitome argues for tonsillectomy.

Though tonsillotomy is an easy method and partially successful in most cases, the tonsillitome alone should not be the instrument of selection, but we should elect the enucleation and complete method, that is, the dissection of the tonsil and its capsule from its attachments, and then the completion of the operation with the knife, scissors, snare, tonsillitome, or, if necessary, the punch. The consensus of opinion is that in tonsillectomy there is less danger of postoperative bleeding than in tonsillotomy. If it is at all necessary to operate upon the tonsil, it is diseased, and should be removed *in toto*.

During the operative procedure the field of operation should not be obscured, either by poor light or by blood and mucus.

The first can be overcome by the aid of the head mirror, or the electric head light, while the second cause can be overcome by rapid sponging of the field with gauze sponges. In this way we can ascertain exactly where the bleeding point is, if the hemorrhage is profuse, and also, of as great importance, the fact that we can see what we have done.

Too much attention cannot be given to an unobscured field in tonsil operations, viz.:

To emphasize the different methods to be pursued in order to obtain as nearly a bloodless field of operation as possible, the following classification is suggested:

(1) Preliminary. I would advocate the examination of the blood, to determine the coagulation time, of all patients presenting themselves for operation. Though it may be possible that many cases may be thus examined unnecessarily in routine work before a positive case is found, still, there are many pathological conditions in which the coagulation time is considerably longer than normal.

In hospital practice this routine can easily be accomplished, the pathologist being called upon to make the examination in detail. In private practice or in dispensary work the coagulation time can be determined very easily by the simple procedure of puncturing the lobe of the ear, after cleaning it with alcohol and ether, allowing a drop of blood to fall on a previously (alcohol-ether) cleaned slide, and at intervals of a half a minute drawing the needle used in getting the blood across the drop, thus ascertaining when clot formation takes place. While it is true that this method is crude, it suffices for clinical purposes. The slide should be kept warm by keeping the under surface in contact with the skin of the examiner. Coagulation should take place in from one and a half to three minutes under normal conditions. If the time is longer it is necessary to go further into the history of the case and determine the exact conditions by further diagnostic methods. In those cases in which the coagulation time is delayed the administration for a week previous to the operation of calcium lactate in 20-grain doses from four to six times a day has proven of benefit, clinically, whether or not from an experimental standpoint, the administration of this drug is of value or not.

(2) During the operation with cases under an anesthetic, the hemorrhage can be controlled by sponging or, after the removal of one tonsil, by placing a gauze sponge against the site of the tonsil, as recommended by Dr. Cohen of Baltimore, or by the use of the tonsil compressor, as devised by Dr. Smith of Philadelphia or Dr. Hurd of New York, or any other similar instrument, or by a suction apparatus.

The posture of the patient is of importance. The head should be in such a position that the best view of the field can be obtained. Either the recumbent, semi-recumbent or the erect positions may be used—depending on the operator's selection. In those cases of removal of the tonsil under local anesthesia the cocaine should be combined with suprarenal extract 1-200, using from ¼ to 1 per cent. cocaine. This gives a field particularly free from oozing.

(3) After operation, that is, immediately after, the site of the tonsil should be sponged as nearly dry as possible and inspected for more than the usual amount of bleeding. Should we find a small artery bleeding, usually a small branch of the ascending palatine, we can stop it by torsion with forceps, or should the hemorrhage be severe, by ligation with catgut.

If the patient is conscious, swallowing pieces of ice will stop a moderate hemorrhage and swabbing the site of the operation with alcohol—provided the hemorrhage is a general oozing—suffices.

An easy method is to place the catgut—a number one or two—in a gauze packer, loosely knotted in a granny knot, with a loop of sufficient size to pass over the hemostatic forceps. The loop is slipped over the forceps and down to the bleeding point, when the gauze packer is removed, thus leaving the ends of the ligature in the operator's hands. The loop of the ligature is tightened and the forceps removed. The reason for using the granny knot is that it can be slipped along itself into place. The anterior and posterior pillars may be approximated by suturing or by the use of the Pierce tonsil hemostat.

Cauterizing agents may be used—such as strong silver nitrate solution or subsulphate of iron—but, as a rule, pressure with gauze sponges soaked in 1-2000 suprarenal extract is sufficient.

Recapitulation. Coagulation test of the blood as a preliminary method and the use of calcium lactate where indicated. Clear view of the field while operating—good light and swabbing. Tonsillectomy to be preferred over tonsillotomy. Suprarenal extract to be used in cases done under local anesthesia. Compression over the site of the operation either by special apparatus or gauze sponge with adrenalin. Torsion and ligation of the bleeding point.

245 West One Hundred and Second Street.

Surgery of the Thymus.—Victor Veau and Eugene Olivier make a study of seventeen cases of hypertrophy of the thymus, from which they have evolved indications for operation and a surgical technique. The functional symptoms that are prominent in this condition are permanent dyspnea, crises of suffocation, and stridor in respiration. There are signs of dysphagia, of vascular compression by the tumor, which are exceptional. The dyspnea is characterized by contraction of the diaphragm, with retraction of the region of its attachment. The permanent dyspnea is caused by compression of the trachea. Sudden crises of suffocation arise, which are made worse by lying down, and intubation does not benefit them. The stridor is laryngeal, due to compression. In some cases the mass of hypertrophied gland may be felt. Radiography and radioscopy give little aid. The only relief is operation, which should be subcapsular thymectomy. This is always partial and leaves behind enough of the gland to carry on its function.—*Archives de Médecine des Enfants.*

THE ARMY AND NAVY ENDURANCE TESTS.

THE wise and judicial remarks of the Surgeon-General of the Army, relative to the harm done to elderly officers by the excessive strains of endurance tests, seem to have had a sobering effect upon laymen both in and out of the service. The first propositions called for such severe effort that they were toned down after General O'Reilly, then Surgeon-General, had shown how dangerous they were, but it now appears that the value of his advice was not fully appreciated and that the tests as finally devised have, in fact, caused serious damage, in several cases fatal, to officers who were of the highest value to the nation and who were sufficiently robust to do duty even in war. This result was predicted, for it is one of the best established facts in practical medicine, and laymen, too, are beginning to understand why many heart or nerve cases are traceable to the irreparable damage of long forgotten strains, and why there are so many such chronic invalids that physicians can specialize on them. There is still more or less ignorance in professional circles, and those who know find it necessary to call attention repeatedly to the fact that the normal senile changes in all tissues are so rapid that the efforts necessary for development or health in one decade of life are harmful excesses in the next. More and more often do we find in current medical literature the statement that, in this sense, men of 45 or 50 are old, and that formerly, when existence depended upon severe physical exertion, they were crowded out of existence by younger competitors. Almost always a careful examination of a man over 40 reveals a disease or damage from prior disease, which indicates that he is on the downward path and must guard his weak point to survive. It is accepted as proved that men now live beyond the period of full physical vigor because they can avoid excessive exertion and that the danger line drops quite rapidly after 35. There seems to be no doubt that the recent enormous increase of deaths from diseases of the heart and kidneys is due in large part to the strenuous life of America. There is then no mystery whatever in the disablement of so many officers in middle life, in spite of, or because of, the fact that they had been noted athletes. It was because of athletics that they kept up the strains too long. Perhaps all of them were overstrained years before, in the period when they supposed themselves equal to the tasks. The present tendency to restrict within safer limits the activities of athletic naval cadets is wisdom based on a solid scientific foundation.

History shows that most officers instinctively keep themselves fit for war and have always given an excellent account of themselves. The public has, therefore, been somewhat bewildered as to the necessity for all this nagging. In addition, as the strains of war are always beyond human endurance and invariably result in a high percentage of invalidism, it is folly to subject men to these strains until it is necessary to sacrifice them in the nation's defense, as the excesses render them less fit. If not actually disabled, they are kept "stale" and have no staying powers. But it is said that the tests have actually been more severe than the strains liable to be encountered in modern campaigns. The naval officers in particular are never required in battle to do the equivalent of walking fifty miles around and around the decks, and a heart sufficiently enlarged to stand a bicycle test is a distinct disadvantage and danger in a mode of life so devoid of exertion as to be possible for even leaky heart valves, providing compensation is established. The naval officer should not have an athlete's heart, and to insist on it is to ruin our highly efficient personnel.

Now that experience has shown what harm the physical tests can do, we hope the whole matter will be laid aside, with the other vagaries of the strenuous life, and more attention be given to the qualities which make officers valuable. It is hinted that a few muscular men have gone through the endurance tests with flying colors, though not possessed of sufficient intelligence for the commands they fall heir to, while professional experts of the highest value to the nation have been killed or retired disabled. The little Napoleon would have difficulty in holding a commission nowadays, and perhaps Cæsar would be eliminated, while the husky barbarians he slaughtered would attain high rank. It is a pity that so little attention has been given to the intellectual side of the matter, and we trust that more will be given in the future to avoid the bitter criticisms which invariably come in such cases from an aroused public opinion. Fortunately there are signs of such a betterment. The War Department authorities have formulated a tentative plan "to maintain a physical condition which will enable officers, especially those approaching the close of middle life, to be always fit for active field service and in condition to perform as high a class and as large an amount of office work as possible." This plan which, we believe, calls for a daily walk of three miles or ride of six, is to be tested by the officers on duty at the Army War College in Washington and at Fort Meyer. Such a plan, when the modifications which experience will probably show to be necessary are made, will be a decided improvement over the annual test, or would be if this test were abandoned. As yet no announcement is made of its abolition, but

now that the War Department is beginning to display reason in the matter we may hope that it will substitute the daily walk for the excessive and injurious annual test. It is more sensible to base the habits of life on the proved fact that after judicious training has developed any ability, physical or mental, efficiency is retained by very small exertion and that if we strain ourselves beyond a rapidly diminishing maximum safe limit we cause irreparable damage. In physical exertion the heart is the sufferer, for it cannot resist much internal pressure, as many a poor invalid has realized too late. A boy may recover from an acute dilatation, but men over 40 rarely, if ever.

HUMANE TREATMENT OF THE INSANE.

A STRANGE residuum of the middle ages during which barbarous practices toward the insane were considered good treatment, consists in the present practice of the care of the insane pending commitment. Under the law, the superintendent of the poor in counties or the overseers of the poor in towns are charged with the duty of caring for the insane in their respective districts, from the time they are noticed and apprehended until they are examined for commitment to a State hospital. The insanity law provides that a temporary paper, consisting of the certificates of two physicians, who are certified examiners, sworn to before a notary, may be prepared hastily and used for the quick transportation and lodgment of a patient in a hospital, if, within ten days, a duplicate paper, properly completed by the addition of the commitment of a judge, follows. Without an hour's delay after the receipt of notification that a patient has been committed a nurse or nurses are sent forthwith to bring the patient to the hospital in the most comfortable and reassuring manner. It is probably due to absence of information as to how such unfortunates can be handled that over five hundred men and women are lodged in jails and lockups in this State, contrary to the provisions of the insanity law. Some superintendents and overseers of the poor are skillful, humane, and judicious men, who take good care of the insane pending commitment; others, unfortunately, either lack initiative or lack information as to how to perform their duties in this respect. Often patients are brought to the hospital from uncomfortable, sometimes filthy and vermin-infested cells, not infrequently occupied in common with persons accused of crime, notwithstanding that this is specifically forbidden by law. In many cases also there is entire lack of provision for attendance on the insane by persons of their own sex, the impropriety and danger of which proceeding to both the patients and their custodians can scarcely be exaggerated. Innocent persons may be exposed to false accusations, from which they may have no opportunity to defend themselves, for many physicians, even those accustomed to analyzing the charges and reports of the insane, believe the stories told by these defenseless women. The danger to the female patient needs no comment. In one instance, a nurse found an insane woman entirely nude in her cell, and the only person to attend to her was a man who handed her food in at each meal.

A Senate bill No. 831, introductory No. 766, has recently been introduced by Senator Cobb, to provide for the substitution of the local health officers for the superintendents and overseers of the poor, in the matter of caring for the insane pending commitment. This bill provides that the health officer shall be paid proper fees and expenses, which shall be determined and allowed as a charge upon the respective county or town by the judge ordering the commitment or hearing the application for the commitment. The bill is approved and endorsed by Dr. Eugene H. Porter, New York State Commissioner of Health, by Dr. Albert Warren Ferris, the President of the State Commission in Lunacy, and by Dr. William L. Russell, the medical inspector attached to that commission. The latter's wide experience with the condition of all the patients recently received into State hospitals renders him peculiarly fit to judge of the present status of this matter, and the proper means for obviating the difficulties and dangers of the situation. The bill is endorsed also by the medical superintendents and managers of the thirteen civil State hospitals, and also by many health officers.

In the interest of ordinary humanity this bill ought to become a law, and its passage would be ensured if the physicians in the State would write to the Honorable George A. Davis, Chairman of the Committee on Judiciary, and to the Honorable George H. Cobb, Temporary President of the Senate, urging that the bill be reported out of committee immediately and advanced rapidly to final passage. The press of the State has alluded to the sad conditions of the uncommitted insane at frequent intervals; but it is still a fairly common occurrence to find these poor sick people spoken of as "prisoners suspected of insanity" or "insane offenders," terms which recently appeared in one of the Buffalo newspapers. The insane are neither paupers nor prisoners, but simply sick people, who deserve the same kind care and treatment as the unfortunate victims of any other form of illness.

EXPIRATORY STRIDOR IN TUBERCULOSIS OF THE BRONCHIAL LYMPH NODES.

INFECTION of the bronchial lymph nodes is now looked upon as one of the earliest pathological pictures in the tuberculosis of infants, the accompanying or antecedent infection of pulmonary tissue often giving very few clinical signs. Infection of these nodes, however, is likewise difficult to recognize in clinical observation, the frequent dry cough, the change in voice and in the size of pupils, the consequences of venous stasis, all being very frequently too indefinite to allow any diagnosis. Of the newer methods, von Pirquet's reaction, if positive in an infant under two years of age, speaks for a tuberculous infection, but does not localize it. Roentgen photographs, though frequently pathogno-

monic in appearance, are difficult to obtain and difficult to interpret. A new phenomenon, observed by Schick among young infants in Escherich's clinic in Vienna, and described by him in the *Wiener klinische Wochenschrift*, Vol. XXIII, No. 5, is therefore of much practical significance. It consists of a respiratory stridor, heard during expiration in a quietly breathing infant. This stridor resembles most the sound heard in bronchial asthma or in capillary bronchitis. The former, however, occurs in paroxysms, while the stridor under consideration often continues without change for weeks or months; capillary bronchitis is usually accompanied by more or less marked constitutional symptoms and by well defined pulmonary signs. Moreover, von Pirquet's reaction serves as a control, being negative in these two affections.

Schick's material is abundant enough to prove the value of the sign he describes, of the thirty-six infants, in whom it was observed thirteen showed tuberculosis of the bronchial lymph nodes at the autopsy. During life twenty-seven gave pathognomonic Roentgen pictures and seventeen gave a positive von Pirquet reaction. In seven children, the diagnosis was not corroborated by any of these control methods, for various reasons, but five of them had other distinct signs of pulmonary and lymphatic tuberculosis. Anatomically, the cause of the stridor proved to be the compression of one bronchus, usually the right, by an enlarged tuberculous lymph node. Schick lays stress upon the fact that in most of these patients the expiratory stridor was the first sign that guided the diagnostician in detecting tuberculosis of the bronchial lymph nodes, which was then further corroborated by photographs and by physical diagnostic methods. The phenomenon is so easily detected that control of Schick's observations and conclusions by other pediatrists should not be long in coming.

Measles and Mice.

In a paper read before the Washington, D. C., Medical Society by A. F. A. King of that city, the suggestion is made that the microbe of measles may be conveyed by the mouse. The paper was published in the *Washington Medical Annals* for March. The theory is ingenious, and has been hinted at before, but at one time, and not so very long ago, it would have been received with complete incredulity and probably with a considerable amount of scorn. Of late years, however, the rôle of animals and insects in the dissemination of disease has been so conclusively demonstrated that he would be a bold and ill-advised man who scoffed at any suggestion, wild as it might seem, which endeavored to trace a connection between an animal and infection. Moreover, it should not be forgotten that Dr. King was a pioneer of the theory that there might be a causal relation between mosquitos and malaria. After all, there is nothing inherently improbable in the idea that mice may be the means of conveying measles to the human subject, and it will be interesting to discuss briefly Dr. King's arguments in support of the theory. Numerous cases are on record in which measles appears to have originated from contact with straw. According to Dr. King, during our civil war it was generally understood that the soldiers in both armies contracted measles by sleeping upon straw. In 1862, Dr. J. H. Salisbury of Newark, Ohio, obtained from wheat straw spores of fungi, which when introduced into the body, produced a disease which appeared to be identical with measles and which conferred immunity upon those who had been inoculated with these spores. True, Salisbury's conclusions seem to have been discredited by subsequent investigations; but if the mouse be admitted as an etiological factor in producing measles, the conflicting results of Salisbury and his opponents may possibly be reconciled, for as Dr. King points out, one may have been experimenting with straw containing mouse infection and the others with straw in which the mouse factor was absent. Is there any coincidence between an increased prevalence of measles and mouse-plagues? Dr. King attempts to answer this question in the affirmative and to show that during the three most notable mouse-plagues of recent times measles was also prevalent in one of the localities at the same time. The scenes of the superabundance of mice were, respectively, Scotland, Thessaly, and Russia during the years from 1892-1895. In Scotland in 1893, when the mouse-plague had reached its acme, the number of deaths recorded from measles was greater than for any previous year for which a record was kept. The author adduces other evidence presumably in favor of the theory, and while confessing that this is for the most part only probable or presumptive, explains how positive evidence might be obtained by experiment. If it is admitted that mouse excreta are the original source of measles, it is easy to conceive that these excreta, when dried by the warmth of houses, crushed by passing feet upon the floor, and dispersed by housemaids' brooms into the air, can readily come in contact with the respiratory and other mucous surfaces. At present, it must be confessed, the case against the mouse as the originator or transmitter of measles is not very strong, but the matter is worthy of further investigation.

News of the Week.

An Outdoor Public School.—Arrangements for an open-air schoolroom experiment in this city have been completed, and the first of the twenty provided for in the appropriation will be opened within a few days. The room selected for the experiment is on the second floor, overlooking the court around which the school is built. On one side windows extending from floor to ceiling will make the room entirely open to the air. Outside these windows a good-sized balcony overlooks the court, on which at intervals the pupils will have light gymnastic exercises. Regular school seats, such as are used in the other rooms, will be supplanted by more comfortable benches. For the stronger children there are separate chairs and desks of varied heights and sizes to accommodate the children of various ages. Besides these are reclining seats, much like steamer chairs, made of canvas stretched on wooden frames. Nourishing food and warm wraps will be supplied to the pupils. The schools are intended for anemic children, not for those suffering from tuberculosis.

A Quiet and Safe Fourth of July for New York.—Mayor Gaynor has decided to let stand the order issued by Fire Commissioner Hayes before he left office prohibiting the retail sale of fireworks in this

city between June 10 and July 10. The sale of fireworks at retail cannot be carried on unless a permit is first obtained from the Fire Department.

A New State Hospital in Westchester County.—On March 28 Governor Hughes signed the Goodwin bill creating the Mohansic State Hospital at Yorktown, Westchester County, and providing that the Governor within ten days shall appoint a board of seven managers, of whom two shall be women.

Dartmouth Medical School.—At a recent meeting, the trustees voted to accept the resignation of Dr. Miles Standish, professor of ophthalmology in the medical school. Three new medical professors were appointed. Dr. William Edwin Butler of Brooklyn, N. Y., becomes professor of medical jurisprudence; Dr. Elliott Gray Brackett of Boston, professor of orthopedics, and Dr. Elmer H. Carlton, clinical professor of diseases of the eye, ear, nose, and throat.

New York Polyclinic Medical School and Hospital.—Among recent endowments to this institution are one of $250,000 by William P. Clyde, and another of $125,000 by Mrs. Helen Hartley Jenkins.

Hospital Accident.—A senior pupil in the training school for nurses in the Long Island College Hospital in Brooklyn died last week of injuries suffered by falling through a freight elevator shaft. She boarded the elevator to take supper to a private patient on the third floor. When starting to leave the elevator her foot caught between the floor of the elevator and the floor of the corridor. The elevator man started it and she fell down to the subcellar, five stories below.

A Coroner's Physician Sued.—A coroner's physician in New York has been made the defendant in a suit for $25,000. The plaintiff charges that the defendant illegally abstracted and retained her son's spleen and heart when he made an autopsy on the young man who came to his death as the result of an accident which ruptured his spleen.

Serum for Rheumatic Fever.—Dispatches from Paris state that on March 30 a paper was read by Dr. Rosenthal before the Academy of Medicine in which the author claimed to have discovered a curative serum for rheumatic fever. The academy has appointed a commission to investigate the subject.

Low Birth Rate in England.—England's birth rate last year was the lowest on record—25.58 per thousand of population.—This is nearly 1.0 below the rate for 1908, which showed a slight increase over 1907, the first for many years.

University of Pennsylvania Alumni Association.—The Medical Department of the University of Pennsylvania began the celebration of Old Home Week on March 28 with a series of clinics and demonstrations. Several former classes held dinners and the banquet of the Alumni Association was held on March 30, when announcement was made of the resignation of Dr. James Tyson from the Chair of Practice of Medicine and the election by the trustees of Dr. David Linn Edsall as his successor, together with the transfer of Dr. Allen J. Smith from the Chair of Pathology to a new Chair of Comparative Pathology, and the election of Dr. Howard Taylor Ricketts of Chicago to the Chair of Pathology, of Dr. Richard Mills Pearce of the University and Bellevue Hospital Medical College to the newly created Chair of Experimental Medicine, and of Dr. Alonzo Englebert Taylor to the newly created Chair of Physiological Chemistry. Tablets in the medical laboratories were unveiled to the memory of Professor Nathaniel Chapman and Professor Samuel Jackson. The following were elected officers of the Alumni Association for the ensuing year: *President,* Dr. Samuel S. Stryker; *Vice-Presidents,* Drs. James B. Walker, George A. Peirsol, Charles W. Burr, George W. Guthrie, Edward Jackson, William A. Edwards, and T. H. T. McKennan; *Historian,* Dr. Roland G. Curtin; *Secretary and Treasurer,* Dr. E. A. Shumway.

Iowa State Board of Health.—A proposition is to be presented to the Iowa State Medical Society in May recommending that the present State Board of Health be abolished and in its place be adopted the system of an appointed health commissioner and advisory board. The purpose of the change is to remove health matters from politics.

The Twenty-fifth Annual Report of the Bureau of Animal Industry of the United States Department of Agriculture has just been published. It is an illustrated cloth-bound volume of 502 pages containing special articles and information of both popular and scientific interest. This report is issued as a Congressional publication, and a limited number of copies are assigned to each Senator, Representative, and Delegate in Congress for distribution among his constituents. The book is on sale to the public by the Superintendent of Documents, Government Printing Office, Washington, D. C. Among the articles of medical interest contained in the book are three on tuberculosis in animals and its relation to man, by Drs. Melvin, Schroeder, and Mohler and Washburn. The subject of hog cholera is discussed by Drs. Niles and Melvin. Dr. Washburn has an article upon the length of time that typhoid bacilli will live in milk. Drs. Lane and Parks discuss the improved methods for the production of market milk by ordinary dairies. Dr. Melvin describes the 1908 epidemic of foot-and-mouth disease. Some of the articles in the report have been issued separately in pamphlet form and can be obtained in this form on application to the Department of Agriculture.

Proposed Missionary Hospital for the Insane in China.—Dr. John J. Mullowney, a medical missionary at the Methodist Episcopal Hospital mission in Peking, China, at a faculty meeting of the Union Medical School was recently elected to teach nervous and mental diseases. Dr. Mullowney states that there is but one hospital for the insane in China, with a capacity of 180 patients. Dr. Mullowney proposes to found a new modern hospital for the insane in the north of China.

Street Accidents in New York City.—According to the report of the National Highways Protective Society there were 21 persons killed and 101 injured during March in the streets. These figures do not include minor accidents not reported by the police or hospitals. Of the 21 persons killed 8 were children.

Automobile Smoke Nuisance.—The chairman of the Nuisance Committee of the National Protective Highways Society held a conference recently with Health Commissioner Lederle to discuss the automobile smoke nuisance in New York City. Dr. Lederle said he had been waiting for some action by the Aldermen, but if no assurance was forthcoming from them the Board of Health would institute proceedings looking to a termination of the nuisance. It is intended to try to make Section 181

of the Sanitary Code applicable to the case. This section says regarding the smoke nuisance: "No person shall cause or allow dense smoke to be discharged from any building, vessel, stationary, or locomotive engine."

Rabies Scare in New York City.—Excitement has been caused in the Elmhurst section of Greater New York by a case of rabies which developed in a dog. The animal before being killed bit ten other dogs, four children, and one man. Last summer the Board of Health agents killed in Manhattan 217 dogs, in Brooklyn 170, in Queens 256, in the Bronx 140, and in Richmond 250.

Smallpox Notes.—It was recently reported that there were in Bay City twenty-five cases of smallpox in eighteen families. The condition is considered to be well under control. During a recent vaccination crusade in Birmingham, Ala., 40,000 persons were vaccinated. The Holland-American Line Steamship *Nieuw Amsterdam* was held at quarantine in New York Harbor recently owing to a case of variola being found on board, and 150 of her passengers were sent to the Government Isolation Hospital on Hoffman Island.

New York Milk Supply.—At a meeting of the Board of Health of New York City held recently the following resolution was adopted: "It is the sense of this board that milk used for drinking purposes should be either properly pasteurized or boiled unless it is what is technically known as 'certified, guaranteed, or inspected milk.'"

American Society of Sanitary and Moral Prophylaxis.—A meeting of this society will be held at 8.30 P.M. on Thursday, April 14, at the New York Academy of Medicine. The paper of the evening, "The Social Evil in New York City, with Reference to Law Enforcement," will be read by Mrs. William H. Baldwin, Jr. Among those who will take part in the discussion are the Rev. Dr. Charles H. Parkhurst, Mr. James B. Reynolds, Prof. Seligman, and Mr. Frank Moss.

The Sixth International Congress of Esperantists will meet in Washington, D. C., during the third and fourth weeks of August, 1910. It is expected that Dr. Zamenhof, the oculist of Warsaw and the founder of the Esperanto language, will be in attendance.

The Sixteenth International Medical Congress.—The General Secretary of the Sixteenth International Medical Congress, which was held at Budapest from August 24 to September 4, 1909, has announced that the members of that assembly will receive their copies of the general report during the course of the month of April. In accordance with the terms of the Congress Regulations, every member thereof will receive a copy of the general volume as well as of that of the section in which he was inscribed. Besides these publications, there will be a copy of the work on the Protection of Child-life in Hungary, kindly presented to each Congressist by the Royal Hungarian Minister of the Interior.

The Third International Congress of Physiotherapeutics was opened at the Sarbonne, in Paris, on March 29, by President Fallieres.

Obituary Notes.—Dr. JOHN P. C. FOSTER of New Haven, Conn., died at his home, April 1, 1910, aged 63 years. He was a graduate of Yale College in 1869 and of the Yale Medical School in 1875, and later was post surgeon at New Haven for the United States Marine Hospital Service. Dr. Foster was very active in antituberculosis work in both State and national societies. In 1908 he was vice-president of the National Society for the Study and Prevention of Tuberculosis after having been a director for four years. He was one of the incorporators of the New Haven County Antituberculosis Association and chairman of the executive committee. Last year he was appointed by Governor Weeks of Connecticut a member of the tuberculosis commission of the State and was elected its chairman. He was a member of the New Haven County Medical Society, the Connecticut State Medical Society, and the National Climatological Society. In recognition of his services in antituberculosis work Yale University conferred upon him the honorary degree of Master of Arts in 1909.

Dr. GEORGE A. EVANS of Brooklyn died at his home, March 31, 1910, aged 65 years. He was a graduate of the Bellevue Hospital Medical College in 1873, and was a member of the Brooklyn Pathological Society, the Medical Society of the County of Kings, and the Medical Society of the State of New York.

Dr. OSCAR COLEMAN DE WOLF of Chester Center, Mass., died at his home, March 28, 1910, aged 74 years. He was a graduate of the Berkshire Medical College in 1857, and shortly after graduation was made demonstrator of anatomy in the college. After the Civil War, through which Dr. De Wolf served as a surgeon to the First and Second Massachusetts Cavalry, he settled in Northampton. Later he moved to Chicago, and in 1877 was appointed Commissioner of Health to that city, a position which he held for fourteen years. From 1891 to 1903 Dr. De Wolf practised in London, England, having previously been made an honorary member of the British Association for the Advancement of Science. In 1903 he returned to his native home of Chester Center, where he died.

Dr. ISAAC H. DIX of Pratt, Kan., died in Salena, Kan., March 21, 1910, aged 73 years. He was a graduate of the Cleveland Homeopathic Medical College in 1869, and a member of the Pratt County Medical Society and the Kansas Medical Society.

Correspondence.

A PROTEST AGAINST NASAL DOUCHING FOR THE PREVENTION OF COLDS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In your issue of April 2, a letter of Dr. Beverley Robinson appeared which makes some justifiable strictures upon the recommendation of the nasal douche as a harmless procedure in the hands of untrained persons (mothers, etc.). These comments are the more justified and necessary because these symposia are held before the largest audiences of women ever assembled for such beneficent purpose, and especially because the douche was not advised for the treatment of catarrh (which would be only a violation of ethics), but for the prevention of catarrh (which I regard as a violation of the principles of sanitation). I confess that though I was present and was shocked and astonished by the advice to apply a nasal douche of normal salt solution "just as regularly as the tooth brush is used," I did not rise in protest. Twice I was on the point of doing so, but I remembered that "discretion is the better part of valor." First, I did not deem it proper to have this lay audience of impressionable women listen to the differing of the doctors, and then I thought of the futility of a protest by a mere general practitioner against a practice so nonchalantly advocated by eminent specialists, whom I myself know and esteem personally and professionally. To place into the hands of an untrained woman such means of injuring the delicate epithelium of the nasal cavity, especially the tender cylindrical epithelium covering part of the turbinated bones, and of infecting an accidentally abraded point by unsterilized water or nozzle, and of

driving water into the Eustachian tube, which is not only possible but probable in untrained hands, would, despite the careful instructions given by the speakers, appear unwise, to say the least. Despite the statement of the eminent laryngologist that otitis media is rarely caused by the nasal douche, I should regard this as a dangerous probability, if I may be permitted an opinion deduced from actual observation. In the early eighties I happened to be physician for eye, ear, and nose diseases in two of our dispensaries, in which I had abundant opportunity of learning whereof I write. I remember that while I was teaching this specialty in the first postgraduate school started in this city, a physician was attacked by a most intense otitis after using a nasal douche, as I had taught him to use it with a weak Dobell's solution, *i.e.* secundum artem.

I enter this earnest protest against "douching of the nasal cavity just as the teeth are brushed" with, I trust, becoming modesty, and with the hope that the result will be similar to that achieved on a previous occasion (*New York Medical Journal*, Jan. 5, 1884), when I had the temerity to oppose, single handed, the dictum of the highest authority in obstetrics, that "every puerpera must be regarded as having passed through a capital operation and, therefore, must receive a vaginal douche of a three per cent. carbolic acid solution several times daily." The pages of your journal and its editorials have recorded this struggle against great odds, for just as in the recent symposium all the speakers followed the lead of the first and principal speaker, so in that memorable discussion in the Academy of Medicine on Jan. 31, 1884, the views of the leading authority were approved by no less than five specialists. The only opponent was the president of the Academy, the late Fordyce Barker, and to his honor, be it said, in closing the discussion Dr. Gaillard Thomas himself bravely said "the arguments which have been used against vaginal injections after normal labor have had great weight with me. You may ask why this change of opinion. I answer, that I strive to mend the faults of yesterday with the wisdom of to-day."

It may be of interest to your readers to mention an incident which demonstrated the genial spirit and professional worth of Fordyce Barker, when I state that he called on me—then a stranger in a strange city—to express his sympathy and to commend my courage in venturing to oppose the dangerous teaching of a high authority. It is the "irony of history" that the gentleman who teaches the nasal douche as an accompaniment to the tooth brush, was present shortly after this discussion at a dinner given by Dr. Barker to Professor Winckel at the Union Club, to which I had the honor of being invited as an advocate of the to me unknown teachings of Winckel. The practitioners of that time witnessed a revolution in postpartum management which was as radical as it was sudden, viz., to keep the finger and instruments out of the vagina. The doctor of more recent period has found this a universal doctrine. And I would that the doctor of today would beware of meddling with the delicate mucous membrane of the nose as he refrains from meddling with the less, far less delicate healthy mucous lining of the vagina. I do not lose sight of the fact that the vagina of the normal puerpera is almost always more or less abraded, no more do I forget that a nose which is daily having a douche cup or nozzle more or less unsterilized poked into it by a mother or still more ignorant nursemaid, may at any time become abraded and infected. *Nil nocere* was taught by the Nestor of Medicine—Hippocrates, and this warning has been sounded by Cantani and all good clinicians, including our own Jacobi in one of his memorable addresses. If modern medicine stands for anything positive, it stands for strict abstention from interference with nature in disease. This abstention is more important still in health. In my propaganda for free cleansing baths I have been made humorously conscious of this dictum by protests against too frequent bathing, voiced on two different occasions by eminent dermatologists who claimed injurious results from too frequent resort to soap and water! If the tough skin is regarded as so vulnerable by men who "know it not wisely but too well," how much more liable to damage must be the delicate mucous membrane of the nose. Compare these structures under the microscope—the one with its pavement-like corneal covering—the other with its waving, tender cilia—and no argument would be needed to defend the latter against insults, mechanical, thermic, or bacterial.

I have written this in no spirit of criticism, but from a sense of duty; it will not, and is not intended to reach the (hitherto happily) untutored women who heard the symposium on the cause and prevention of colds, but this protest may serve to remind some of my colleagues to instruct their clients against the pernicious practice of prophylactic nasal douching. With the exception of this special symposium I heartily approve of this method of instructing the lay public in the "causes and prevention of disease." Not only is it an evidence of an awakening on the part of the public, but it illustrates that the medical profession has so broadened in spirit that it is no longer regarded as unethical to address lay people from a medical platform, as it was in my earlier life. The conduct and management of these meetings are especially creditable to the chair(wo)man, whose tact and grace were conspicuous throughout.

Simon Baruch, M.D.
51 West Seventieth Street.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SPECIAL DIPLOMAS AND R.C.P.—TROPICAL MEDICINE—PERICARDITIS—ATYPICAL PNEUMONIA—HOSPITAL REPORTS—OBITUARY.

London, March 18, 1910.

The spread of specialization has long been a sore point with general practitioners, and even in the consultant ranks there are many who deprecate it. But it continues to grow, and those engaged in the several specialties are no longer afraid to defend their position and practice. Since public health was recognized as a distinct branch by the issue of diplomas as additional qualifications, other branches have demanded equal treatment. The Royal College of Physicians is one of the bodies issuing such a document, but refused an application to do as much for tropical medicine, although as a compromise it agreed to attach a certificate to the diplomas of candidates showing adequate knowledge of the subject. The "mad doctors" rather too often insist on the ignorance of the general practitioners of mental disease and the latter retort that their accusers think everyone insane except themselves. The specialists in question have induced the college to consider their desire for a "diploma in psychiatry" to be granted after the general license to practice has been obtained—to be, in fact, a sort of additional or special diploma, similar to that in public health, which they dub the medical younger brother Jacob, who supplanted the elder Esau of psychiatry. The college held an "extraordinary comitia" on the 3d inst. to discuss the matter. The specialists were in full force and urged the claims of psychiatry from various points of view; I think their weakest was the assertion that the junior staffs of asylums needed it to overcome their indifference to the study of the highest scientific side of their work. It is generally held that these gentlemen are well paid and have plenty of time for study, and it is certain that laboratories have been provided for many asylums and large sums of money voted for the study of the pathology of insanity and for scholarships in connection with it. I am inclined to think that the seniors in their zeal for psychiatry cast an unjust slur on the juniors. It might be retorted that the seniors made their own reputations as juniors. A more reasonable statement put forward was that sometimes appointments to the superintendency of asylums had been given to doctors who were not specially skilled in psychiatry. But the blame of such a thing should be laid on the shoulders of those who do it, and are we to admit that an examination would remedy such objections as these? The multiplication of diplomas and of consequent examinations is more than an inconvenience or even a nuisance; it inflicts many an injustice, and while most people demand the reduction of the number of qualifying bodies it is scarcely prudent to provide them with the means of increasing their fees. If only a proof of extra study is wanted, why not institute a class of honors, as at the universities?

The chief objection to the proposal was admirably put by Dr. Norman Moore, who maintained that the license of the college guaranteed that the holder had the knowledge necessary to begin practice and was competent to enlarge his knowledge in any direction. If more psychiatry was required it should be got by adding to the curriculum—not by depriving their licentiates of one way of getting their living. Their way ought not to be barred in any direction by special diplomas, which would lead the public to think them unfit to practice any specialty.

The comitia, after further discussion, agreed to appoint a committee to report to the college.

Dr. C. W. Daniels of the London Tropical School is giving a course of lectures to merchants and per-

sons proposing to go to the tropics. This course follows up that of Professor Simpson, which I reported to you a fortnight ago. The main object of Dr. Daniels is to show those going to the tropics for the first time that those regions are not so bad as they have been painted. Taken all 'round, he found life there more pleasant. There was, he admitted, more ill-health, but that was not necessary. The mortality has been enormously reduced by a proper mode of life and simple precautions, *e.g.* Jamaica, once with a terrible mortality, has become a health resort. In India the death rate of Europeans has fallen from 69 per 1,000 in 1858 to 16 among our troops. The golden rule for those going to the tropics was moderation in all things. A man who had contracted malaria might recover perfectly if he lived properly. The lecturer gave demonstrations of how malaria was acquired, its development in the blood corpuseles, the transmission by mosquitos, and so on. He then told the story of prevention and how on some plantations the cases had fallen from hundreds a year to about a score.

Pericarditis has occupied two evenings of the Medical Section of the Royal Society of Medicine. It was introduced by Dr. S. West, who considered at some length the question of paracentesis. In rheumatism the effusion usually produced no urgent symptoms, and as soon as absorption began it was rapid, so operation was not called for. Signs of adhesion were not left even after large effusions. Paracentesis was not a difficult operation. When necessitated an exploration with a small needle should first be made. He had never had any accident. The exploratory puncture might be made at any site indicated by signs. He had, for instance, tapped at the base on the left side and even to the right. Where the choice was free the safest place, he thought, was the fifth or sixth intercostal space outside the left nipple line, but well within the area of dullness, for here, owing to the displacement of the heart upwards and the distension of the pericardial sac outwards, was the widest space between the heart and the seat of puncture. All the fluid possible should be taken. Reaccumulation was not common, but if it did occur puncture could be repeated. In some recorded cases the operation had been performed many times.

Dr. Lees observed that the amount of fluid in rheumatic pericarditis was less than commonly supposed and might be absent. Clearly the cardiac dilatation was due to the causes of the pericarditis.

Dr. Ewart said that in future when cardiac effusion was diagnosed we must try to find out to what extent of cardiac dilatation was also present.

Sir John Broadbent said that effusion was more frequent and less dangerous in adults than in children. Extreme cardiac dilatation, with pericardial adhesions, was common in rheumatism, but effusion was comparatively rare. Diagnosis based on rapid increase of the area of dullness was therefore liable to deceive.

Dr. Herringham had seen the heart punctured in two cases through a diagnosis of effusion. In neither case it did harm.

Dr. Pasteur hoped the orthodiagraph would be more used. If pericarditis inhibited movement of the diaphragm that would explain some physical signs at the left base in effusion.

Dr. Porter Parkinson said the differential diagnosis between effusion and dilatation was always difficult, sometimes impossible. In such cases he suggested a surgeon should be called in to cut down slowly, feeling his way and finding out the actual conditions before opening the pericardium.

Dr. C. Ogle had seen in a case of distended pericardium the external jugulars pulseless and permanently distended, and thought this immobility, so distinct from the pulsation common in dilated heart, might be due to an obstruction by pressure to the entry of blood into the heart.

Dr. Ironside Bruce showed *x*-ray photographs in which the pericardial outline was sharp, and Mr. Lister remarked that small quantities of pericardial effusion could be diagnosed by these rays.

Dr. Poynton said large effusion was rare in children. He had never known puncture necessary in a rheumatic case.

Dr. Alex. Morison said twelve cases out of forty-four of pericarditis with adhesion had no endocardial lesion, but were due to extension of inflammation from neighboring tissues. The chief clinical interest was in the diagnosis. He deprecated active interference in non-purulent cases and a limited effusion. If exploration became necessary, he preferred removal of a bit of cartilage and cautious incision to puncture with a needle. He mentioned a case in which such an operation had shown that needling would probably have been disastrous.

Atypical pneumonia was the subject of a paper by Sir John Broadbent at the Medical Society of London on the 28th ult. He found that in adults the cases were mostly associated with influenza. The onset was insidious and the diagnosis difficult, as the pyrexia might be intermittent and the physical signs delayed. The pyrexia might continue for weeks without definite crisis, and there would then be progressive wasting. In some cases empyema or malignant endocarditis might develop; in others, after a long period of septicemia, recovery took place without further complications. In children symptoms suggesting cerebrospinal meningitis, especially in cases beginning at the apex, might give rise to difficulty; so a case of protracted lobular pneumonia might be mistaken for tuberculosis. In contrast to this typhoid, which in children often ran an atypical course, might be masked by bronchopneumonia complicating it.

Dr. Reginald Miller followed with a paper on protracted pyrexia in pneumonia in children. He said in 217 hospital cases 55 (25.3 per cent.) showed fever for more than ten days, and this high percentage, he thought, might be due to the fact that the longer it lasted the more likely was the child to be sent to the hospital. The primary cases were 126, those secondary to bronchitis 91. There was not much difference in the proportion of protracted cases between the two groups; primary, 26.19 per cent; secondary, 24.17 per cent. The mortality of protracted cases was increased threefold, being 30.9 per cent., as against only 9.87 per cent. in the unprotracted.

Dr. Camac Wilkinson said tuberculin in adults would settle the diagnosis of doubtful cases. Dr. Theodore Williams did not consider that reaction to tuberculin proved tuberculosis. Dr. S. West held that reaction proved the patient to be tuberculous, but not that the inflammation from which he suffered at the time was of that nature.

Many charities are holding their annual meetings and most of them appealing for more funds. Yesterday University College Hospital had to report a falling off in legacies and to confess that the new hospital costs £10,000 a year more to maintain than the one it displaced. An appeal for £11,000 is being urgently made.

Yesterday, too, was the meeting of the Ventnor Hospital for Consumption, and Lord Roseberry, presiding, repeated a little grumble he made last year, that the King's Fund contributes nothing, although half the patients are sent from London.

The Lord Mayor presided at the Royal Hospital for Diseases of the Chest at the ninety-sixth annual meeting. This is the oldest hospital in Europe for consumption, etc. Last year the in-patients numbered 718, the out 25,254. The expenditure was £6.586. The invested income is only about £200, so a large sum has to be looked for from subscriptions.

Brigade-Surgeon E. J. Boulton, late A.M.S., who has died, first served in the Navy and was awarded the medal for the Baltic expedition, 1855. He joined the Army Medical Service in 1860, served in the Zulu war, 1879, was in the engagement at Gingindhlovn and the relief of Ekowe, receiving medal and clasp. He retired in 1866.

Dr. Cecil Edgar Fish of the Vale of Cluyd Sanatorium died on the 7th inst. He was a Cambridge graduate in arts and medicine, 1889-1894, and took the double London qualifications in 1893.

Dr. William Haig Brodie, a retired M.O.H. in Sussex, where he held other appointments, has also died. He was D.P.H., 1891, and F.R.C.S., Eng., 1895, but graduated in Edinburgh as early as 1881.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 24, 1910.

The Present Status of Vaccine Therapy.—W. Tileston speaks of the value of prophylaxis with the vaccine therapy, and then discusses its use in localized infections. He says of vaccines that they will not and could not be expected to cure all cases, for they depend for their effect on a responsive power on the part of the patient. If this is lacking, no benefit can result. Moreover, the vaccine, if it is to be of use, must contain the organism which is causing the disease process. The practice of injecting dead

bacteria of all sorts and frequently a mixture of various bacteria in all sorts of conditions with the hope that by some lucky chance the right organism might be hit upon, cannot too strongly be deprecated, for it is calculated to cast discredit on vaccine methods. To sum up the present situation, in certain localized infections, particularly those due to the staphylococcus and to the tubercle bacillus, vaccine therapy has clearly proved its worth and stands on firm ground. In general infections it has not thus far shown results which are distinctly better than those obtained with other forms of treatment. There can be no doubt that there is going to be improvement in the methods of preparing vaccines and in the principles governing their administration. Vaccine therapy is still young and we may expect much improvement in the future. The field of immunity is very fertile and is being assiduously cultivated.

Local Anesthesia (Neumann) in Ear Surgery.—After commenting on the Schleich method of infiltration anesthesia, J. J. Hurley refers to a paper by Heidenhain which furnished the immediate stimulus for Neumann's work. The latter found it possible to operate on the frontal sinus by the subperiosteal injection of solutions of cocaine and adrenalin, the fluid being absorbed through the bone canals and lymph spaces, anesthetizing at one and the same time the soft parts, bone, and mucosa. Contraindications are two: First, the existence of a subperiosteal abscess, and, second, very neurotic persons, because of the psychial effect of consciousness and not because the anesthesia is insufficient. The paper details the methods of injection and follows up the gradual improvements in aural practice obtained by it in view of increasing experience. The present status of the plan is thus summarized. Neumann's anesthesia fulfills all the requirements of Heidenhein, and stands forth as one of the greatest advances of modern otology. It has no design on the ether or chloroform market, and desires to be on only the most friendly terms with both relatives. In mastoid work, when general narcosis is contraindicated, it needs no defense. It seeks to limit the radical exenteration to those cases in which there is a strong presumption of mastoid or brain involvement. It promises to do away with the chiseling out of a healthy mastoid to arrive at a chronic ear, and it claims the intratympanal field as its own.

New York Medical Journal, March 26, 1910.

Some Dermatological "Manias" and "Phobias."—W. S. Gottheil refers among others to the question of syphilis, saying that while we have no absolute criterion as to its cure, the disease is being cured every day. He is of the opinion that it is becoming milder either from a change in the virulence of the spirochete strain or from a gradual change of soil or from improvement in treatment, especially of the secondary infections, which are responsible for the ill effects ascribed directly to the malady. It is when the patient contemplates marriage that syphilomania develops in its severest form. When a patient has had three years of adequate treatment and has passed an additional year without treatment and without symptoms, he may in the author's judgment safely contract marriage. He regards infection from public women as comparatively infrequent, considering the amount of specific disease among them. The modern fear of lepra is without foundation. Fortunately, the public is coming to entertain more sensible ideas on this subject. The lepra infection under the conditions occurring in this country is very feeble. The danger to others is very small. Leprosy is probably not hereditary, though, of course, children living with leprous parents are especially exposed to the contagion. Advanced cases, of course, belong in hospitals, but it is needless to incarcerate cases early and make of them a public charge. In addition to the phobias mentioned, there are various other personal peculiarities, such as subjective bromidrosis, etc., which appear in practice from time to time. In such cases the psychiatrist may find that the symptom is merely part of the beginning of deeper seated and more serious pathological changes.

Typhoid Carriers.—R. C. Rosenberger summarizes much of the recent literature on this subject. The greater number of observers now believe that not only the gallbladder, but in addition the urinary bladder and intestines are the habitat of the bacillus for which the bile appears to be a particularly favorable medium, especially after admixture of protein matter as a result of inflammatory changes during the disease. Carriers may be acute, chronic, or intermittent. The bacillus may be absent from the excreta for a month or two and then reappear. All of this information requires the existence of rigid sanitation in connection with each case. A suspected carrier should have monthly examinations made for six months. When found positive, isolation should result, but this is hardly possible in a city or community while perfectly feasible in an asylum or institution. Great care must be employed in making the necessary tests. In favor of the inactive sera the following reasons are advanced: First, in some active sera are substances which exert an anticomplementary action in the control tube without antigen, so that the rule of using in this tube double the dose of serum to be tested cannot be applied. These substances are destroyed in heating to 56° C. In this way we get a pure fixation reaction, and not a summation of anticomplementary action. Second, inactivating destroys human complement, and we know more nearly the exact dose of complement present in the test. In comparing active and inactive serum, I have seen weak reactions with the active serum which were strong with the same serum inactivated. Here the weak reaction seemed to be due to the presence of human complement. In such a complicated test it would seem advisable to obtain each factor in as pure a state as possible. Inactivating the human serum gives us the antibody in this condition. The advantage of the Noguchi principle is the accurate dosage of all the other factors. Inactivating, which adds but little to the work involved, gives us a constant method of dosage of human serum, and its uses render the method as accurate as it is possible to attain when we are dealing with such unstable substances as products of vital processes.

Operation for the Cure of Hammer Toe.—R. E. Soule describes the following operation: After the usual preparation of the foot for operation and after the Esmarch bandage has been applied, a skin incision, one and one-quarter inches long, is made at the outer aspect of the plantar surface of the toe, the center of which incision is at the flexed joint. The skin flaps are dissected laterally, sufficiently to expose the underlying structures. The incision is continued through the subcutaneous structures, being careful to expose the digital branch of the artery and the nerve and to prevent their injury while continuing the dissection down to the joint. The sheath containing the flexor tendons is now dissected free from the joint and held aside sufficiently to allow of the removal of the articulating joint surfaces with the chisel, observing due care to have sufficient flat surface at right angles to the shafts of the contiguous bones as a result of the arthrodesis. No bone suture is necessary. The subcutaneous structures are now allowed to fall back in place and are held by a few fine buried catgut sutures. The skin is closed with interrupted chronic gut and dressings applied. A plaster-of-Paris bandage, fixing the toes in hyperextension, making the flexor tendons tense, thus holding the bony surfaces of the phalanges operated on in close apposition and in a straight line is finally applied. After ten days the plaster-of-Paris is split and the dressings are removed sufficiently to expose the field of operation. Then the dressings are restored and maintained in the original position for six weeks. The patient is allowed up on crutches after the first dressing. The author says that the advantages of this operation over that performed on the dorsal surface of the foot are: (1) No sensitive scar is left to chafe in the shoe. (2) There is less chance of interrupted healing of wound, due to the pressure on skin wound necessary to keep the toe extended. (3) The securing of the aid of the shortened flexor tendons taken advantage of in forcing the end to end contact of the bones. (4) Bony contact is maintained throughout healing by the position of the overextension of the toes.

Journal of the American Medical Association, March 26, 1910.

Surgery in Neurasthenics.—Stuart McGuire emphasizes the importance of refusing to operate on a neurasthenic patient unless the symptoms are clearly due to organic disease, and also the necessity, if an operation is undertaken, with either latent or developed neurasthenia, of protecting the nervous system from psychic and physical shock. This will require not only proper preliminary preparation but also careful and often long postoperative and posthospital treatment. The surgeon must remember that his aim is to cure not merely to cut, and if neuroses exist he must remember that if they exist alone, operation will be liable to do harm, while if they exist with organic disease, operation may do good, but great care must be taken not to aggravate the nervous symptoms. This is especially true of patients who have previously been subjects of other operations. Two separate preliminary examinations should be made of every surgical patient; the first for diagnosis to determine the condition to be corrected, the second for prognosis, to determine the safety of the operation and the chances of a complete cure. Several specialists may be required to aid in this, as sur-

geons are not always qualified to do all the special work that is required. The preparation of the patient should be both physical and psychic, and in the past too much attention has been paid to the first and not enough to the second. Not all patients are in good nervous and physical condition and we are too apt to underrate the important effects, psychic and otherwise, of local operations, on the patient's health. Hence a longer stay in the hospital should be insisted on in many cases and when patients return to their homes they should be placed under the oversight of their family physician rather than left with simple verbal or written instructions to be carried out by themselves. McGuire thinks that, with the rapidly increasing amount of surgery being done, there should be an educational movement started for the study of the many peculiar factors involved. Physicians should take part in this and the subjects should include the question of a proper dietary, best method of bowel regulation, and treatment of bladder irritation, the hours of sleep, the amount of exercise permissible, and hundreds of other questions relating to occupations, habits, bodily hygiene, etc. When surgeons, he says, appreciate the influence of neurasthenia on the result of an operation, and when the family physician is educated in the details of posthospital treatment and given legitimate work with proper compensation, then and not till then will there be harmony in the profession and the greatest good accomplished to the greater number of patients.

Fat and Its Uses.—G. M. Niles describes the part played by fat in the human organism under its material, esthetic, and psychic aspects. As compared with protein, fat is often unappreciated or misunderstood and unduly blamed for sins or delinquencies of other body foods. From 15 to 20 per cent. of each healthy body is composed of fat, and its chief sources are the starches and sugars, though certain fats are directly utilized. The weight of present opinion is in favor of the view that fats are completely decomposed in the intestine, and that the fatty acids formed are absorbed, either as soaps or in a solution brought about by the bile. As a source of energy for the development of heat, fat may be described as quickly available, but not so lasting as some other substances. By its concentrated fuel power it saves other tissues, especially the albuminous ones, from overoxidation, and is valuable as a reserve force. Moreover, by its presence the protein is better enabled to do its work in tissue building, and as a storage of energy for emergencies it is of great importance. The last material use of fat is to serve as a protection of the body from injury and cold. It forms an outer cushion for the frame. From an esthetic standpoint, the physiological and orderly distribution of fat in the connective tissue makes all the difference between beauty and ugliness. In considering the psychic rôle of fat, we should specially bear in mind, Niles says, its reserve function in relation to active vital processes. A liberal deposition of fat is one of Nature's wise precautions to enable us to bear some of the trials of life. It has been known from earliest antiquity that fat people are more contented and optimistic than lean ones, and the supply of fat may be compared to the ample bank account of a busy and provident man. Niles says that he believes he is correct in asserting that a physiological reserve of fat, by its very presence, exerts a quieting and reassuring influence on the vital forces most concerned in constructive metabolism, while its lack leads to a physical discontent and unrest which sooner or later reacts on the disposition, developing into that pessimism and temperamental discontent so often seen in lean people.

Vaccination.—J. F. Schamberg's conclusions are as follows: "1. Vaccination, when properly and adequately employed, protects one against smallpox. Even those intimately exposed to the disease, as physicians and nurses in smallpox hospitals, may be rendered completely immune against smallpox by vaccination and revaccination. 2. Vaccination protects against smallpox in the same manner that one attack of the smallpox protects against a second attack. Vaccination has the special advantage in that the immunity which it confers against smallpox may be renewed when it becomes impaired or exhausted. 3. Vaccination, in order to confer protection, must be genuine; the mere production of a "sore arm" is of itself no proof that the subject has been successfully vaccinated. The vaccination must run a definite course before a protective substance is left in the body. 4. Smallpox may develop in vaccinated persons if they have permitted years to elapse without being revaccinated. 5. Vaccination and revaccination universally applied are capable of exterminating smallpox as an epidemic disease. The experience of Germany during the past thirty-five years proves this. 6. In isolated instances, individuals in a generally well-vaccinated community may develop smallpox because their protection is imperfect as a result of the use of an inert virus or because of some other fault of technic. These cases, however, will never appreciably influence the prevalence of the disease in such a community. 7. Smallpox was an ever-present and terrible pestilence in the days before vaccination. In most civilized centers it is to-day a relatively rare disease. This change has been effected almost exclusively by vaccination. Epidemics of smallpox prevail from time to time when the spark of infection is introduced into the community and a sufficient amount of unvaccinated combustible material exists to lead to a general conflagration. In countries where vaccination is neglected, as in Persia, Asiatic Russia, etc., etc., smallpox is still a death-dealing scourge. 8. The foes of vaccination commonly refer to the infrequency of smallpox at the present day and to the remote liability of contracting the disease. They forget that the relative security which we now enjoy is caused by vaccination. This security can be made absolute or it can be largely destroyed according as vaccination and revaccination are generally employed or generally neglected. 9. The dangers connected with vaccination have been greatly exaggerated by the opponents of this measure. Vaccination causes an abrasion of the skin, and in rare instances this wound, like other wounds, may become infected, especially when neglected or maltreated. With the selection of a proper virus and care of the vaccination site during and after vaccination, the risk in any individual instance is an entirely negligible quantity.

Aural, Nasal, and Throat Symptoms in Diabetes.—O. J. Stein says changes occurring in the mucous cavities of the head and neck in diabetes are by no means uncommon. In the mouth, evidences of perverted nutrition are frequently found. The secretions become distinctly acid and act on the necks of the teeth, exposing the deeper and more sensitive parts to the ever-present infection in the mouth, hence spongy and bleeding gums and aching teeth are symptoms of importance in diabetes, the existence of which is often recognized by dentists from the mouth symptoms. Aphthous stomatitis, thrush, a large red tongue sometimes with black fur in the middle, hyperemia of the mucosa, which often presents a glazed appearance and feels dry, are frequent symptoms. If acetone is present in quantity its odor is imparted to the breath, and the patient himself may be aware of the sweetish taste. Sialorrhea has been observed in some individuals with pancreatic disease. In the throat there is a dryness which is not to be confounded with pharyngitis atrophica. In the dry pharyngitis of diabetes the mucous membrane is usually red and glazed in appearance. This symptom is considered important in connection with others in the diagnosis of diabetes. Tuberculous appearing ulcers appear occasionally, but they heal readily, and therefore have not been considered by Freudenthal as tuberculous. Externally a reddening of the nose has been observed in diabetes but as to intranasal symptoms nothing characteristic has been noted. Stein, however, thinks that there are many cases of intranasal irritation that might show a relationship to diabetes. The manifold variety of ear symptoms is surprising to the casual observer. A common symptom is furuncles in the external ear, and otitis externa diffusa chronica may be present, especially the desquamative type. Eczema auris is not uncommon and may be very extensive. In all such cases, Stein says, he makes a urine examination for diabetes. Gangrene may rarely occur. Suppurative ear disease is a serious complication in diabetes, but not necessarily alarming. Some authorities hold the opinion that a primary mastoiditis may occur. An otitis media that appears suddenly without apparent cause should lead to an investigation for diabetes. In Stein's observation, these cases are more painless than usual and the mastoid is always involved. Both ears may be affected. He says that suppurative otitis media and suppurative labyrinthitis are commonly associated in diabetes, and brain complications have been many times observed. We should be alert in all diabetics with otitic involvement for symptoms of panotitis. Lastly, he mentions neuritis of the acusticus which, according to Benninghaus, is most frequently caused by diabetes.

Syphilis of the Liver.—W. F. Cheney gives the history of a case in which the diagnosis pointed strongly to tuberculosis, both in the history, the physical findings, and the temperature curve. The tuberculin reaction, however, was negative and there was conclusive evidence of syphilitic infection. In favor of this as a cause of the condition, and of the case being one of late occurring congenital syphilis, was the fact of the frequence of liver symptoms such as existed in this case and the agreement of the clinical features with those of liver syphilis, as well as the positive reaction of the mother to the Wassermann test. The usual

congenital stigmata such as Hutchinson's teeth, interstitial keratitis or its scars, deafness, bone deformities, and constitutional defects usual in such cases, were absent and the double pleuritic effusion which existed is not accounted for except by a coincident gummatous lesion in both pulmonary bases, but there was no proof of this. He calls it, therefore, only probably, late congenital syphilis.

The Lancet, March 12 and 19, 1910.

The Clinical Significance of Gastric Hypersecretion and Its Connection with Latent Disease of the Appendix.—W. Soltau Fenwick says that the disorder known as "hypersecretion" is distinguished from all other functional perversions of the stomach by the fact that a secretion of gastric juice occurs in the intervals as well as during the periods of digestion and, therefore, is practically continuous. In conclusion he says: (1) Hypersecretion of gastric juice invariably depends upon an organic lesion, which usually takes the form of a chronic ulcer of the stomach or duodenum, calculus in the gall-bladder, or latent disease of the appendix, although it is probable that future investigations will prove that pancreatic calculus, tubercle of the cecum, and carcinoma of the appendix are also capable of producing it. Of the last named, one case has already come under his observation. This disorder of secretion is merely the physiological expression of a reflex irritation of the gastric glands, and is therefore not entitled to be regarded as a disease. (2) The continuous flow of hyperacid gastric juice, whatever be its cause, always excites severe inflammation of the stomach, and is very liable to be followed by ulceration of that viscus or the duodenum. This secondary ulceration is at first superficial in character and may not be demonstrable on examination of the exterior of the stomach. Minute hemorrhagic erosions, capable of producing alarming hematemesis and melena, are usually associated with, and caused by, this abnormality of the gastric secretion. (3) Latent disease of the appendix as a result of former acute inflammation is accompanied by a peculiar form of digestive disturbance. In this condition subacidity of the gastric juice with an absence of free hydrochloric acid is the rule. (4) With the exception of hemorrhage, all the symptoms that are regarded as pathognomonic of duodenal ulcer are in reality due to the gastric hypersecretion that always accompanies this lesion. It follows, therefore, that a severe example of hypersecretion may as a rule be safely diagnosed as a case of duodenal ulcer. (5) Contrary to the usual belief, carcinoma of the pylorus is sometimes accompanied by extremely well marked hypersecretion. In such cases the morbid growth develops with extreme rapidity and violent hemorrhages, due possibly to digestion of the tumor, are exceptionally frequent.

Some of the Commoner Forms of Chronic Rheumatism (Fibrositis) and Their Treatment.—Arthur P. Luff says that in the great majority of the so-called cases of chronic rheumatism, the essential pathological change is an inflammatory hyperplasia of the white fibrous tissue in various parts of the body, to which the term "fibrositis" has been very aptly applied. Local fibrositis may result from several causes of which the following are the commonest: Cold, damp, and wet; extremes of heat and cold; local injuries; absorption of irritating toxins from the alimentary tract; tonsillitis and pharyngitis; influenza; febricula. Among the various forms he mentions muscular rheumatism, an affection which is always a fibrositis; lumbago which is a typical form of fibrositis; Dupuytren's contraction, a localized fibrositis caused by postural use of the hand; fibrositis of the plantar fascia; pads upon the finger joints constituting a chronic form of localized fibrositis; and chronic villous synovitis, in fact, not a form of fibrositis, but referred to because the treatment is similar to that of other forms of chronic rheumatic conditions. In the treatment of the different forms of fibrositis salicylates are of little curative value. Aspirin is of decided use in relieving the pain. Iodide of potassium is a most valuable drug in the treatment of fibrositis. In properly selected cases fibrolysin (combination of thiosinamine and sodium salicylate) is a very useful drug to employ. It is possible that if the direct stinging with bees is of any efficacy in the treatment of rheumatism, it is simply due to the action of formic acid as a counterirritant. In the early stages of an acute fibrositis hot fomentations are useful. Afterwards one of the best external applications is a mixture of equal parts of chlorid hydrate, camphor, and menthol. Diaphoresis is especially beneficial at the onset of the attack, and heat is of the greatest use, dilating the peripheral vessels, lowering blood pressure, causing diaphoresis, and relieving pain. Massage is most useful in the later stages. No special dieting is required. Porous linen underwear should be worn.

The Treatment of Vomiting.—J. Snowman says that every case of vomiting will fall into one of three groups which may be distinguished as local, toxic, and reflex. In the treatment of vomiting the first point to determine is whether it is an incidental symptom of an acute illness or whether it is a cardinal feature of some chronic disease. In the treatment of acute illnesses the management of the dietetic treatment should be by less drastic measures than virtual starvation; the aim should be to make a strict milk diet easily tolerated. The ordinary available measures for the treatment of vomiting are very numerous; but nausea may be allayed occasionally by sips of hot water or by sucking fragments of ice. Bismuth is an excellent drug for use when the vomiting results from gastric irritation, but in other circumstances little is to be expected from it. Creosote, iodine, and carbolic acid may be grouped together as a series of drugs which allay vomiting when suitably employed. Aconite must be given in large doses; it then numbs the reflex centers and acts as a powerful sedative to the peripheral nerves in the gastric mucous membrane. It is one of the best of drugs suggested for the vomiting of pregnancy. One-third of a grain of cocaine will occasionally put a sudden stop to vomiting, and is one of the most effective remedies available for sea sickness. Hydrocyanic acid is another drug with a reputation in gastric vomiting. Opium is our most valuable remedy for vomiting, however, especially in those cases which are persistent and exhausting. It should be given hypodermically.

Note on the Crepitation Heard in the Third Left Intercostal Space in Some Cases of Mitral Stenosis.—C. W. Cunnington says that in a large proportion of cases of mitral stenosis crepitations are heard in the third left space. The area over which they appear is scarcely larger than a half-penny, placed over the third space close to the sternal margin. It may run down to the fourth or up to the second space. The crepitations disappear when the breath is held. They are heard only on inspiration, and are more frequent in women, but this form of valvular trouble is more frequent in women, anyway. They may be present on a given day and absent on another, and are more liable to be present when the heart is distended. They have been found when the compensation is perfect. These sounds are not due to accompanying tuberculosis, which is rare in this form of cardiac trouble. They are evanescent, do not spread, and are strictly limited in position. One is compelled to believe they are due to the heart condition. In mitral stenosis the left auricle is distended and there is from time to time some pulmonary congestion of a passive nature due to obstruction at the mitral valve. These sounds are heard over the site of the left auricle, and it is probable that they arise in a small edge of lung tissue pressed on by the dilated auricle or appendix. Treatment designed to relieve the auricular distention causes them to disappear.

Chorioepithelioma of the Testis.—The patient of O. C. Cruner was a man of twenty-five years, with enlarged left testis, which he had had for five months. The swelling occupied mainly the epididymis. The cord was not thickened and there were no adhesions between the swelling and skin. The growth was about one inch in diameter, was excessively vascular, and occupied the middle of the testis, which apparently formed a thin layer all around it. Syphilis and tuberculosis were excluded and castration was performed. Recovery was without incident. The rest of the paper is taken up with the results of microscopical investigation. The cells of the living parts of the tumor were remarkably polymorphous. Some were spindle shaped, others tailed at one end, others polygonal, others quite round, and others like the cells of spheroidal-celled carcinoma. There were also marked variations in size, the first-mentioned shape being small and the last mentioned very large. The character of the cells strongly recalled that of decidua malignum. Their close examination revealed a similarity on the one hand to sarcoma cells and on the other to the cells of a spheroidal-celled carcinoma, so that the tumor might be called a sarco-carcinoma.

The Treatment of Labor in Contracted Pelves with Special Reference to the Justifiability of Pubiotomy.—G. F. Blacker considers four classes of pelvis. In the first are placed those with a conjugate diameter of 2 2/5 inches or less in which it is impossible to deliver with any degree of safety to the mother either a living or dead child through the natural passages. The second class includes those pelves with a diameter from 2 2/5 up to 3 inches, in which a living child cannot be delivered, but in which there will be no undue difficulty in delivering a dead child. A third class has a diameter from 3 to 3 3/5 inches, and is most important of all. In such instances premature labor is often performed. The author discusses especially pubiotomy

and detailed studies show that the risks after it are less than with symphysiotomy so far as concerns immediate maternal mortality, yet the possible sequelæ of the operation are both numerous and serious. Hemorrhage as a rule is not excessive. The most important and serious injuries are tears of the vagina and vulva. Manual dilatation of the vulva and vagina before operation will lessen the frequency of this accident. Injuries of the bladder are not uncommon, and lead to infiltration of the tissues by the urine or to vesicovaginal fistulæ. Infection of the wound is the rule rather than the exception and occurs in at least half the cases, the morbidity varying from 40 to 60 per cent. Septic phlebitis is not uncommon. Remote sequelæ are not of so much importance. The union of the fragments is often fibrous, yet interference with locomotion is quite uncommon. Prolapse of the genitals and incontinence of the urine is not uncommon. The author offers the following as the right solution of the problem: In any case in which it is considered inadvisable to perform cesarean section or in which this operation is rejected by the patient and in which the induction of premature labor has been followed by the birth of a still-born child on one or more occasions, the patient may be allowed to go to full term and, if necessary, pubiotomy may then be performed. In many cases of this nature spontaneous delivery might occur, a result which is attended with a minimum of risk to both mother and child. While cesarean section is ordinarily safe, yet pregnancy does occur from time to time in which abdominal section would not be safe, and the woman might prefer pubiotomy to the destruction of her living child. If the patient is in labor when seen and the head fails to engage at the superior strait or is arrested at the brim, then if moderate traction with the high forceps fails, in place of the forcible delivery of the head through the brim, which entails a fetal mortality of 40 per cent. or a higher one with version, a cesarean section should be performed, while if the case be considered unsuitable for this, pubiotomy may be substituted for craniotomy of the living child. Pubiotomy should be undertaken only if it is certain that the child has not been in any way imperiled and in view of the various complications which may follow, it is not an operation for private practice, but should be undertaken only in hospital.

British Medical Journal, March 10, 1910.

Causes and Treatment of Functional Dyspepsia.—David Drummond says that while it is a matter of scientific interest to diagnose accurately the special form of indigestion with which one has to deal, it is of greater practical importance to discover the cause and to point the direction in which relief may be obtained. The investigations of the secretory activity of the stomach, followed by the prescription of an appropriate diet and acid or antiacid remedies, are valuable in many cases for giving relief, but are only too often insufficient for a cure. The great majority of cases of functional dyspepsia are due to obvious causes, errors of diet, bolting of food, dental deficiency and imperfect mastication, irregularity of meals, chronic bacterial intoxication, or they may be secondary to Bright's disease, phthisis, or other chronic debilitating disease, but a few of the causes are apt to be elusive. The subjects of excessive eating or drinking are apt to be reticent and much may depend upon the ability of the physician to secure their confidence and to learn their personal habits. The patient may be indiscrete in the quality of his diet as well as in the quantity. In the matter of special diet there was a great temptation for the physician to skate on the thin ice of quackery and to insist upon the most minute details. It was well within the mark to state that some of the most distinguished physicians had lowered both themselves and the profession by undue exactitude in the matter of dietetic details. It was most undesirable to encourage any patient to dwell anxiously on the details of diet. In ordinary cases it was well to keep along broad lines of information and advice. There is a class of patients in whom mental disturbance produced dyspepsia. These were to be distinguished from those commonly known as dyspeptic neurotics. It is common for both the doctor and the patient to attribute depression to the dyspepsia, when the dyspepsia is really induced by the depressed state of mind brought about by other conditions. If the environment or life circumstance that is responsible for the depression can be removed the dyspepsia is soon cured. If the environment cannot be changed, the patient may be encouraged to take a different attitude toward the disturbing circumstance, or a brighter view of life. One of the most useful therapeutic agents in stomach cases is rest in bed. This measure is often effective whether the excessive exertion has been physical or mental. A number of neurasthenic cases will only be benefited by rest and isolation from home influences.

Reflex Pain in Diseases of the Abdominal Viscera.—After reviewing the anatomical and physiological factors which enter into a consideration of this subject, A. Ernest Maylard calls attention to the fact that if some powerful and exaggerated stimulus arises from an organ, not only are the cells specifically connected with the sympathetic in the cord greatly excited, but also those neighboring ones associated with the sensory nerves; hence it comes about that pain is often felt in the area of the abdominal parietes over the region of the affected organ. Not only may the cells in the immediate continuity be excited, but other cells more remote, and the distribution of the pain may become more diffuse and distant. His chief reason for thinking that in bowel disease we have to deal with really a splanchnic pain is that one usually fails to obtain any evidence of a cutaneous or muscle hyperalgesia. Nature seems to make an exception in her method of dealing with the bowel when implicated in obstructive conditions as compared with her protective measures in certain diseases of other parts. It matters not where the viscus is situated within the abdomen nor where the lesion is located in the viscus, the initial acute seizure is most frequently felt in the midline, although variations will exist regarding the particular spot in this line. The explanation of the fact that in nearly every instance the pain is referred to the middle line is explained on the basis that the cells in the cord which receive the afferent fibers of the sensory nerves contained in the lower six intercostals are abnormally irritated. Without attempting to differentiate clinically between lesions causing pain in the same spot, he gives a sort of classified list of the diseases which may be expected to cause reflex pain in certain definite areas. 1. Perforation of a gastric or duodenal ulcer, rupture of the gall-bladder, acute hemorrhagic pancreatitis, cause acute pain to be felt in the epigastrium. 2. Perforation of the appendix vermiformis or of the small intestine, ruptures, strangulations and obstructions from various causes, embolism or thrombosis of the mesenteric vessels, etc., cause acute pain to be felt in the region of the umbilicus. 3. Rupture in tubal affections, including extrauterine pregnancy, cause acute pain to be felt in the hypogastrium. While diseases of the abdominal viscera may give rise to reflex pain located in one or other of the anatomical regions into which the abdomen is artificially divided, all reflex pains experienced in these particular regions do not necessarily signify diseases of the abdominal viscera.

The Effect of Abdominal Compression in a Case of Very Rapid Heart.—This case is reported by W. Gordon. The patient was a man, 68 years old, who was thrown down by a large motor car which backed onto him. The attacks of "paroxysmal tachycardia" seemed clearly consequent on his accident, as well as his flatulent indigestion. Ten days after the accident the pulse rate was 180. At no time was there dyspnea, cardiac dilatation or murmurs, distension of veins, or edema, except in a thrombosed leg. At this time he noticed that during full inspiration the feeble, rapid pulse became absolutely obliterated. Then a stout flannel binder was tightly applied over the abdomen. From this time on the pulse returned to an ordinary rate, stronger and not intermitting. The effect of the binder can best be explained by its effect on the splanchnic circulation.

A Red Line on the Gums.—G. Arbour Stephens has had the privilege of examining about 900 men employed in works where lead ores are handled, and was particularly struck with the fact that a large percentage of their gums showed a distinctly red line. This red line was due, in his opinion, to an enlargement of the papillæ at the edge of the gum. The atmosphere in which these men worked was probably charged with particles of an irritating nature, and this was the source of irritation. The conclusion that one naturally arrives at from such facts is that the so-called lead line is no proof of lead in the system, but that it appears in workers whose gums have been irritated by particles other than lead.

Calcium Lactate on the Nose and Throat.—Fernandez describes for the first time in Cuba the advantages of the lactate of calcium as a prophylactic measure to prevent hemorrhages in the operations on the nose and throat. He reviews the history of the drug, since it was first described by Wright and declares himself to be convinced that the only way this drug acts is by directly increasing the coagulability of the blood. He has employed it very extensively as a preventive and in no case has seen his hopes unfulfilled. He uses large doses. He has also employed it in the treatment of nasal hemorrhages with excellent results and has seen it employed in pulmonary hemorrhages with satisfactory results. In postoperative hemorrhages the effect is marvelous and almost instantaneous.—*Chrónica Médico-Quirurgica de la Habana.*

Book Reviews.

Arthritis Deformans: Comprising Rheumatoid Arthritis, Osteoarthritis, and Spondylitis Deformans. By R. Llewellyn Jones, M.B., Lond.; Fellow and Member of Council of the British Balneological and Climatological Society; formerly Medical Officer Royal Mineral Water Hospital, Bath. With 38 full-page plates. New York: William Wood & Company, 1909.

To a difficult task the author brings a wide clinical experience and an extensive knowledge of the writings of others. The subject has always been a baffling one, and, in spite of the attention it has received in recent years, it is still full of mystery. This book, while containing some new material, rests its claim for attention mostly on its complete exposition of the facts that have hitherto been set forth, together with its author's interpretation of them. The references at the end of each chapter are numerous and enlightening, and place within the reach of the reader a ready access to a wide bibliography. To one, therefore, who wishes to take up the study of this class of cases, the work will be invaluable. The author considers his subject under two main divisions: rheumatoid arthritis and osteoarthritis, including under the first those cases which Goldthwait and others have considered under the separate heading of infectious arthritis. There have been many attempts to classify these diseases, but until we know more of their essential nature, probably none will be generally received. The book is divided into five sections. The first contains an introductory and historical chapter, and another on classification; the second is devoted to rheumatoid arthritis; and the third to osteoarthritis. The fourth section deals with spondylitis deformans, which the author views as presenting four types: the von Bechterew type, rhizomelic spondylosis, osteoarthritis, and rheumatoid arthritis. The fifth section takes up arthritis deformans in children. Each section except the last contains its appropriate chapters on etiology, morbid anatomy, diagnosis, treatment, etc. Although, as in most works on this subject, the histological pathology has not received the attention it deserves, from a clinical standpoint and as a reference handbook the book is most commendable.

Infectious Diseases. A Practical Text Book. By Claud Buchanan Ker, M.D. Ed., F.R.C.P. Ed.; Medical Superintendent City Hospital, Edinburgh, and Lecturer on Infectious Diseases to the University of Edinburgh. London: Henry Froude, Oxford University Press, 1909.

This latest addition to the series of the Oxford Medical Publications is by a man who, from his official position as superintendent of the Edinburgh City Hospital, which admits to its wards all forms of infectious diseases, is well qualified to write upon the subject. The book, which is of over 550 large pages, covers in a thorough manner the clinical aspect of not only the contagious diseases of childhood, but of typhoid, typhus, smallpox, relapsing fever, erysipelas, and epidemic meningitis, as well. The subjects of bacteriology and pathology are barely touched upon, the entire efforts of the author having been directed to the discussion of diagnosis, prognosis, and treatment, as these questions have been brought up to him in his own experience. Space is not given to the various theories of treatment, only those methods with which the author has had personal experience being given at any length. Where, however, the work of others has been adopted, full credit and honest criticism are given. The work is illustrated with many most excellent photographs and not a few products of the new art of color photography. The latter, though possibly slightly more vivid than nature, at least illustrate the points desired in a forcible manner. The book is well printed and well bound. The book is, taken all in all, a most masterly discussion of the clinical aspect of the infectious diseases, and makes a most valuable addition to their medical book shelf.

Röntgenatlas der Lungentuberculose. Von Dr. Otto Ziegler, Dirigierender Arzt der Heilstätte Heidehaus bei Hannover, und Dr. Paul Krause, I. Assistentarzt an der Heilstätte Heidehaus bei Hannover. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1910.

This volume consists of eleven pages of text, discussing the use of the *x*-ray in the diagnosis of tuberculous disease of the lungs, describing the limitation and the possibilities of the method, referring to the care in interpretation of the shadows and their significance, and urging that the *x*-ray is of value only when associated with the ordinary method of examination; and of a series of *x*-ray photographs, which make up the main body of the book. These latter are exceptionally fine examples of the result of the röntgenologist's art. Each shows strikingly some phase of the tuberculous disease of the lungs, and in the series of sixty-one full-page plates practically every stage of the condition is exemplified. Particularly striking are the series of plates which demonstrate the frequency with which tuberculosis originates in the glands of the hilus and spreads thence through the parenchyma of the organ. Opposite each plate is given a short abstract of the history of the patient, whose chest is exhibited, the physical signs, and in those cases which ended fatally the autopsy protocol. Following this is a brief description and explanation of the picture itself. The book impresses one with the tremendous strides which have been made in recent years in the *x*-ray examination of the lungs. It teaches its lesson forcibly and clearly, and can be recommended as a most valuable addition to the library of röntgenologist and student of tuberculosis as well.

Diseases of Infants and Children. By Henry Dwight Chapin, A.M., M.D.; Professor of Diseases of Children, New York Post-Graduate Medical School and Hospital; Supervising Physician of the Children's Department, New York Post-Graduate Hospital; Attending Physician to the Willard Parker and Riverside Hospitals; Consulting Physician to the Randall's Island Hospital, and to St. Agnes' Hospital, White Plains, and Godfrey Roger Pisek, M.D.; Professor of Diseases of Children, University of Vermont; Adjunct Professor of Diseases of Children, and Attending Physician to the New York Post-Graduate Medical School and Hospital; Attending Physician to the Darrach Home for Children. With 179 illustrations and 11 colored plates. New York: William Wood and Company, 1909.

In writing this book, which is intended for the medical student, the authors have attempted to sail the difficult course between the Scylla of the compend and the Charybdis of the verbose system of pediatrics. Their aim has been to give the essential facts which the student must learn in order to be competent to treat sick children. In order to accomplish this, but little space is devoted to the theory of disease, or the why and wherefore of treatment. The student is told that if certain conditions exist he shall do thus; and, if others are present, he shall do so. The result is a book which, though not such as a pediatrist would find interesting as consecutive reading, accomplishes the purpose for which it is intended, to give the student the necessary knowledge in a brief form, and accomplishes it well. The book will teach the student the elements of the treatment of sick children, but will probably not teach him to think for himself, or to take any especial interest in the subject of pediatrics. The use of tables and graphic representations for easy reference is made with especial frequence, which makes the book useful to one wishing to learn the gist of a subject in the smallest possible time. The work of the publishers is to be commended. The type is large and clear, the paper good, and the illustrations, except possibly for a tendency to too great vividness in the colored pictures, are excellent. The book can well be recommended to the student who wishes his knowledge served to him in a clear, concise form.

Handbook of Obstetrics. By R. Cadwallader, A.M., M.D., Assistant in Obstetrics, University of California Medical Department, San Francisco, Cal. Philadelphia: F. A. Davis Company, 1908.

This volume is an effort to put into a small volume, which will fit into a coat pocket, the essentials of obstetrics. It, however, differs from most pocket obstetrics in that the author has not contented himself with describing the three stages of labor, but, in the small space allowed him, has touched upon embryology, physiology, pathology, sociology, and even philosophy, and on every possible occasion has taken the opportunity to express his personal opinion upon whatever subject happened to be under discussion. This rambling method of expressing personal opinion seems somewhat out of place in a handbook of obstetrics, as, for example, where, in speaking of abortion, after listing the possible sequelæ, the author says: "It is a crime seldom mentioned by Protestant ministers, who seem too wrapped up in contemplation of glories to come to look aside and give the warning advice their congregation needs and who often sin through ignorance." Such a statement is undoubtedly quite true, but belongs more to a society of moral prophylaxis than to a handbook of obstetrics. Where the author confines himself to the subject of obstetrics, he seems to know what he is talking about, and to express himself fairly well, though at times in a somewhat awkward diction. The illustrations are more remarkable for their quantity than their quality.

Society Reports

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 28, 1910.

THE PRESIDENT, DR. JOHN E. WEEKS IN THE CHAIR.

Resolutions.—Dr. E. ELIOT HARRIS, chairman, committee on Legislation, offered resolutions which were seconded and passed, opposing Senate Bill No. 278 and Assembly Bill No. 385, conferring upon the Board of Regents of the University of the State of New York the power of supervision of experiments on living animals. This proposed law was unnecessary as the present law which limited animal experimentation to incorporated institutions was sufficient for all practical purposes. A second resolution was in favor of the bill appropriating $583,000 for buildings and other constructive work in Letchworth village, Rockland County, New York.

Medical Practice Laws: A Review of the Legal Restriction of Medical Practice and of Certain Conditions Existing in New York.—Dr. FLOYD M. CRANDALL read this paper (see page 611).

MR. CHAMPE S. ANDREWS said there should be established a Medical Unity Bill, permanently established, under which should come every sort of physician under one standard; then each could practice any kind of "pathy" or "ism" which their common sense dictated. The question, however, now confronting them was, how much preliminary education should be required before a man should be allowed to practice upon his fellow. This brought to his mind one thought; competition formed the basis of elimination of men in all the walks of life, but he thought it was a pity that competition should come in when either physicians or lawyers were considered. There were a great number of men in the profession of law creating competition which made it extremely difficult for most of them to earn a decent living, and the same condition was true in the medical profession. He thought that the least paid man to-day for the work that he did was the doctor, and next to the doctor the lawyer. Men should be eliminated before they came out in the struggle for the almighty dollar, and he wished that there was some system by which men intending to study law and medicine could be eliminated so that those who were left could have enough to live on, with enough money to go around. The demanded preliminary education favored this and worked for the better protection of public health.

Some Remarks on Deafmutism, with a Demonstration of Methods of Treatment.—Dr. EDWARD W. SCRIPTURE said that by deafmutism they should understand a condition of deafness, either total or partial, which was followed by failure to learn to speak or by loss of speech already learned. The inability to speak was the result of the deafness, and not of any defect in the speech mechanism. Congenital deafmutism was attributed mainly to heredity and consanguinity; also to alcoholism, syphilis, differences in the ages of the parents, and to the diseases of pregnancy. Acquired deafmutism was due chiefly to meningitis. It also frequently followed scarlet fever. Other diseases, like measles, diphtheria, typhoid fever, mumps, influenza, etc., sometimes produced it. Mental awakening was the first step in the training. The mind of the deaf mute was often in a backward condition because he did not fit with his surroundings. The exercises included mimetic movements, as well as various games; in this way the child's attention, observation, imitation and initiative construction were developed. The speech development proceeded along lines that he illustrated in an abbreviated form with a group of four deaf mutes. Three of these were born deaf; the other became partially deaf at the age of three years; through the lack of the use of the vocal organs he had lost what speech he had; he had attended a school for deafmutes where the sign language was used. Breathing through the nose and mouth were first taught. The low position of the tongue was necessary for proper speech, and this was taught by showing the position and using the mirror, and by a breath exercise. Tongue gymnastics were next used to limber up and train the muscles which had never received proper development. The tongue training was introduced preparatory to the use of various consonant sounds. The vibration of the vocal cords was taught by feeling; the pupil placed his hand on the teacher's chest and also on his own. He thus learned to make a tone. The physiological alphabet consisted of a set of diagrams giving the typical positions of the tongue and lips for the chief sounds of language. Combinations of consonants and vowels were read at sight, and through these combinations words and sentences were developed. Lip reading of words and sentences was taught by having the patient watch the teacher's lips while she distinctly enunciated some word. When the deafness was acquired after the person had learned to speak, the teaching of lip reading should begin at once. Two boys were presented; they became deaf at the ages of 13 and eight respectively; they were now 17 and 12; they readily understood nearly everything that was said to them and were able to talk fluently. The unnatural character of the voice of the congenitally deaf mutes was the one drawback; still it was better to be able to understand well and to speak fairly well, than not to be able to do either. In closing Dr. Scripture showed a curious case of sensory aphasia coming on at the age of seven years after scarlet fever. The man's hearing was perfect but he had lost all understanding for the words he heard. His intellectual condition was excellent. He did not go to school and never learned to read or write. Apparently he had motor aphasia. Some questions he understood if he could see the lips of the speaker; he had thus of his own accord begun to learn lip reading. It was Dr. L. Scripture's belief that this patient had no motor aphasia and that he should be taught lip reading just as if he were a deaf mute.

Chronic Catarrhal Otitis Media and Otosclerosis: Etiology, Pathology, and Prognosis.—Dr. W. SOHIER BRYANT said that the etiology and pathology of chronic otitis media and otosclerosis were best considered under two headings, catarrhal and trophotoxic. The catarrhal group included the cases caused by disturbances of the mucous membrane of the upper air tract which affected the middle ear in two different ways, by local inflammation of the middle ear cavity, with or without exudation, and by disturbances of the ventilation and drainage of the middle ear through the tuba auditiva which caused anemia or congestion and accumulation of exudate or excreted material. The tropho-toxic group included the cases caused by trophic and toxic disturbances which affected the mucous membrane and subjacent ligaments and bone of the middle ear leading to defect of the middle ear sound-conducting mechanism by hypertrophy and atrophy of these tissues, and by ankylosis of the mechanism. The starting point of the trophic and toxic changes in the ear was either general, local in the ear itself, or was found in the nasopharynx, in the sympathetic nerves supplying the upper air tract, or in unbalanced internal secretions. The pathological changes, hypertrophic or atrophic, produced by either variety of causes, were practically the same. The changes were hypertrophy of the mucous membrane and the mucoperiosteum, the formation of bands and adhesions, and fibrous hyperplasia of the drum membrane. The hypertrophic affections of the middle ear interfered with the sound-transmitting function of the middle ear. In the hypertrophic cases, the thickening

became changed to atrophy and thinning, with loss of elasticity; later on there was a deposition of lime salts and ankylosis with consequent rigidity. The tropho-toxic changes affecting chronic catarrhal otitis media and otosclerosis were similar to the hypertrophic and atrophic changes of the catarrhal variety. There was also a rarefying vascular osteitis. The prognosis in chronic catarrhal otitis media, when no treatment was given, indicated a gradually increasing impairment of hearing with an increase of the tinnitus, and finally a total loss of hearing. In the tropho-toxic group the prognosis was less favorable; there was as a rule more rapid loss of hearing with remissions and loud varying tinnitus, with final total deafness. The prognosis was bad in the cases where there was bony occlusion of the labyrinthine windows. In conclusion Dr. Bryant said that, in a broad statement, the following was true: Except in two classes of cases, *i. e.* (1) those cases so far advanced that the deafness necessitated using a loud voice at a foot or two distant from the patient, and (2) the extremely rare cases of the toxic group, in which the etiological factor could not be definitely determined, the hearing in cases of chronic catarrhal oritis media and otosclerosis could be satisfactorily improved by carefully following the indications.

The Treatment of Chronic Catarrhal Otitis Media and Otosclerosis.—Dr. Edmund Prince Fowler said that the present methods of treating chronic catarrh of the middle ear were not satisfactory, and there were many reasons. Prophylaxis was usually neglected because the onset of the disease might be insidious and patients neglected treatment. Great numbers of acute cases tended to chronicity from their very inception, and adhesive processes might develop after a few exacerbations or relapses. Comparatively few patients could spare the time or money necessary for treatment. Means should be devised which would enable patients to obtain at home treatment to supplement that gained at the hands of the surgeon. Contributing factors to chronicity received but a cursory examination. The main symptoms they were called upon to relieve were tinnitus and impaired hearing. If the noises were high pitched, continuous and but little influenced by treatment, it was probable that the labyrinth was coincidently affected. The degree of deafness was likewise dependent on the amount of obstruction to sound waves in the middle ear mechanism, and on the concurrent labyrinth changes. To improve the deafness for spoken words was their chief aim. In otosclerosis patients frequently hear better in noisy places. For the great variety of dry catarrhs any treatment was of transient or little avail if they did not diligently see to it that, besides the special, the general well-being of the patient was improved. In exudative catarrhs, inflations of air into the middle ear were especially efficacious, but in chronic catarrhal processes the results from inflations alone were very uncertain. Nevertheless, some form of inflation was indicated, and he used Politzerization and catheterization depending upon the permeability of the tube, and in strength depending upon this and on the tension and strength of the membrana tympani, and on the force necessary to accomplish results. In using the Politzer bag, in cases difficult to inflate, it was all important to bring the nasopharynx air-pressure to the maximum at the moment the tubal muscles tended to dilate the orifice of the tube, as otherwise the air pressure would prevent a satisfactory deglutition, or coming late would expend much of its force into the pharynx, mouth, and esophagus. Strictures of the Eustachian tube, if not organic, might be more or less benefited by air inflations, but in those failing the bougie must be resorted to. As a rule, connective tissue strictures were not permanently benefitted by dilatation. Electrolysis might be used in connection with the Eustachian bougie. Pneumatic massage of the middle ear by way of the external auditory canal was of real value when combined with the other methods. Artificial supports to the relaxed drum membrane were beneficial. Operative measures in the middle ear at present were not much in vogue. Of the utmost importance in catarrhal otitis was the treatment of pathological conditions in the nose and nasopharynx. Properly executed nasal douching would greatly benefit many nasophrayngeal diseases, and thus also the otitis. Dr. Fowler closed his paper with a brief description of his improved nasal douch and his automatic middle ear inflator. Middle ear splints he used because they furnished a means of limiting movement of the drum and ossicles, a greatly desired action.

Nonsuppurative Affections of the Internal Ear.—Dr. John McCoy divided his subject into three parts, the anatomy, the physiology, and the pathology of the internal ear. After considering the anatomy of the cochlea, the semicircular canals and the vestibule, he said that the function of the cochlear portion of the auditory nerve was for the purpose of receiving and distinguishing noises and tones, and that this was essentially the organ of hearing. The vestibule and semicircular canals had to do with equilibrium. The symptom of irritation of the cochlear nerve was tinnitus. The symptom of destruction of this nerve was deafness. The symptom of irritation of the vestibular nerve was nystagmus and disturbed equilibrium. The symptom of destruction of this nerve was loss of excitability. When speaking of diseased conditions of the internal ear one was apt to think first of Ménière's disease. Ménière's case was that of a young girl who was suddenly attacked with loud noises followed by deafness and also accompanied with marked dizziness, vomiting, and nystagmus, and it was found that this resulted from hemorrhage into the cochlear and vestibular portions of the internal ear. The auditory nerve was more affected by drugs than any other nerve of special sense, and a neuritis of this nerve frequently followed the administration of quinine, salicylic acid, morphine, alcohol, and tobacco. The neuritis might be due also to certain infectious diseases. The following pathological changes were produced in the internal ear: hyperemia, hemorrhage, or a change in the ganglion cells. The function of the auditory nerve was more often arrested by general diseases and chemical changes in the blood during infectious diseases than the optic, gustatory, olfactory, or sensory nerves. The changes in the nerve taking place after certain infectious diseases were edema of the center or along the course of the nerve, or ecchymosis, hemorrhage, inflammation and destruction of the connective tissue, with the formation of new tissue at the nerve terminals. Parotitis and spinal meningitis had a great tendency to involve the auditory nerve. A number of cases of complete deafness had been reported following mumps, the reason for which had never been well demonstrated, but this was probably due to a metastasis along the course of the auditory nerve, such as existed sometimes in the breasts, testes, or kidneys. In cerebrospinal meningitis the nerve center had been found in a condition of atrophy and fatty degeneration; the intracranial course of the nerve had been found bathed in pus. The cochlea and vestibule had been found filled with pus, and the cochlea and vestibule had been found in various stages of inflammation and new tissue and bone formation. In such diseases as measles and scarlet fever there was formed a thrombophlebitis and arteritis which produced a destruction of the nerve elements. The internal auditory artery, if suddenly involved by an embolus, resulted in a sudden onset of the symptoms of irritation and destruction of the cochlear and vestibular nerves. The internal ear was affected reflexly from the pneumogastric nerve and its branches. It was also affected by traumatism; in old age by apathy, senile degeneration, and chronic endarteritis.

Dr. Lester Mead Hubby said that tenotomy of the tensor tympani tendon was rarely of advantage. Cases with extreme retraction, together with Ménière's syndrome, had been benefited by this procedure. There were four forms of nystagmus etiologically considered, namely, spontaneous, rotational, caloric, and compressive. A better name for the first would be, in his opinion, autonystagmus. It had an irritant basis just as much as the other forms and should, therefore, not be called spontaneous. The subject of deafmutism was too much neglected by the profession. He called attenton to three methods of treatment, the oral, the manual, and the mixed method.

Dr. John D. Wright called attention to the importance of the right place, the right training, and the right time in the treatment of these deafmutes and he reported a couple of interesting cases.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held February 15, 1910.

Dr. C. N. B. Camac in the Chair.

Chronic Hemolytic Jaundice.—Dr. Lewis A. Conner said that this subject of long standing jaundice had had a good deal of new light thrown upon it during the past three or four years in the discovery that certain cases of chronic jaundice had their origin, not in any disturbance in the liver itself, or in any gross obstruction to the larger bile passages, but apparently in the blood itself, in an abnormal tendency to hemolysis, and it was upon hemolysis in connection with chronic jaundice that he and Dr. Roper wished to speak. Three adult cases were reported briefly, one in which the condition of chronic hemolytic jaundice had existed for twenty-two years, one in which it had existed for eighteen years, and one for about five years. In two of these cases operations had been performed under the mistaken idea that they were cases of cholelithiasis. There were two types of chronic hemolytic jaundice, one, the congenital type, which was originally described by Minkowski, with a definite tendency to run in families; the other, the acquired form which developed in late childhood or in adults. In chronic hemolytic jaundice there were certain distinguishing and characteristic features separating this form of jaundice from that caused by mechanical obstruction to the output of bile from the liver. In the first place the jaundice was not of a very intense grade and was subject to marked fluctuations. Sometimes there might be no jaundice at all; at other times there might be exacerbations of the jaundice. No matter how deep the jaundice was there never was any bile pigment (bilirubin) in the urine, but there was a great abundance of urobilin. This was quite a characteristic feature, the absence of bilirubin from the urine, and the presence of much urobilin. In the second place there were no evidences of any deficiency of bile in the intestines. On the contrary, the stools were often bright yellow or greenish and contained not only stercobilin in abundance but bilirubin itself. There was in fact a polycholia. Another feature which distinguished chronic hemolytic jaundice from most of the chronic forms of jaundice which were due to obstruction was that the spleen was very much enlarged, a splenomegaly; it also differed from the obstructive forms of jaundice in that there was an absence of all the ordinary evidences of the toxic action of the bile. Itching was absent; bradycardia, which was so common in the other types, was not present; there was no emaciation; there were none of the cerebral disturbances which went with the obstructive forms. Again, in chronic hemolytic jaundice there was a pronounced difference in the behavior of the blood. In chronic obstructive jaundice the blood cells were more resistant to hemolytic agents than the normal blood, whereas in the hemolytic type the red cells were much more fragile than the normal cells; the hemolysis was due to changes in the red cells and not to any increased hemolytic action in the serum or plasma. Another point he wished to emphasize was that this class of cases of chronic jaundice was often associated with pain which simulated the pain of cholelithiasis and was not benefited by operation. Such cases must be recognized and attention paid to them.

Dr. Joseph Carles Roper described the method of Hamberger for determining the fragility of the red cells. He also presented charts to show the action of normal corpuscles against salt solutions, against sera, and also one showing Widal's permanent granulation stain. The blood of the cases of chronic jaundice showed well marked fragility of the red cells, as compared with normal blood. The sera showed no hemolytic power and its tonicity was normal. Stained by Widal's method the blood of these patients showed many "sick" cells.

Dr. C. N. B. Camac asked Dr. Conner if fever and local tenderness were present and if the development of the jaundice had any relation to the enlargement of the spleen. Was enlargement of the spleen a constant feature? Was it chronic? What were the gastrointestinal disturbances?

Dr. Conner replied that fever was usually lacking, although occasionally in the exacerbations there might be a little fever for a few days. In some of the more severe cases they ran a slight grade of temperature, and sometimes it might be quite high. Generally these patients were not what one could call invalids. They were simply jaundiced people. Tenderness was present only in those occasional crises when the liver was somewhat swollen. There might be some tenderness there and occasionally tenderness over the spleen. Gastrointestinal symptoms were not uncommon. As yet they had not arrived at any satisfactory explanation as to why the increased hemolysis should be characterized by such a degree of jaundice. Widal had discussed its pathogenesis very fully and was inclined to consider the possibility that the bilirubin might be formed directly from the hemoglobin of the blood without the intervention of the liver—*i.e.* that it was a true hemotogenous jaundice.

The Incidence and Signification of Smooth Atrophy of the Base of the Tongue.—Dr. Douglas Symmers read this paper. In analyzing the records in 623 autopsies he found that the presence of acquired syphilis had been determined in 75 cases, the diagnosis having been based upon the occurrence of characteristic secondary lesions in the skin and mucous membranes, the presence of atrophic pigmented scars, gummata in various localities, and interstitial visceral inflammations, especially in the liver in the condition known as hepar lobatum, and in chronic interstitial orchitis, upon syphilitic orchitis, or upon various combinations of the above lesions, or upon parasyphilitic diseases, such as tabes dorsalis. Of the 75 cases of syphilis thus encountered, smooth atrophy at the base of the tongue occurred 64 times (85 per cent.). In 55 cases the atrophy was complete, and in nine partial. In the great majority of cases the base of the tongue was perfectly smooth or nearly so, scarring having been met with in a few instances only. In seven of the 75 cases secondary lesions were present. In three instances these lesions were active, and in all the lymphoid follicles at the base of the tongue were hyperplastic, while in the remaining four cases the secondary lesions were well advanced in the process of healing. Of these latent secondary lesions the base of the tongue was moderately atrophied in three cases, while in the remaining case the lymphoid follicles were hyperplastic. In four of the 75 cases of syphilis

parasyphilitic lesions were present, and of these the tongue was completely atrophied in two. In 64 of the 75 cases chronic syphilitic lesions were present, and of these the base of the tongue was completely atrophied in 52 cases, or 81 per cent. There was partial atrophy in seven cases; in two cases there was no change, and in three the lymphoid follicles were hyperplastic. From what was known of the changes in syphilis in general and partly from the above observations it might safely be assumed that hyperplasia of the lymphoid tissues at the base of the tongue was not an infrequent phenomenon in the active secondary stages of the disease. It appeared to be evident that these changes were often followed in course of time by atrophy and connective tissue replacement, the latter process sooner or later advancing so as to include certain numbers of the serous glands and muscle bundles in the deeper portions of the base of the tongue, ultimate contraction eventuating in the condition known as smooth atrophy. There seemed to be no histological evidence in support of the view advanced by Lewin and Heller that smooth atrophy was the result of the healing of ulcerating gummata; rather it was a simple replacement fibrosis occurring most often in late acquired syphilis, it was true, but, nevertheless, quite independently of regional gummata. In this respect it presented much that was common to the syphilitic process as observed in other tissues. In his experience it appeared that genuine smooth atrophy of the base of the tongue was the result of syphilis, that statement being based upon the examination of the tongue in a considerable number of both non-syphilitic and syphilitic subjects, where he had yet to find a genuine case of smooth atrophy that was not associated with definite anatomical signs of syphilis in some other part of the body. On the other hand, there were numbers of cases of long standing syphilis which presented no evidence of atrophic, sclerosing changes at the base of the tongue. In fact, the tongue in certain syphilitic individuals might be well preserved or the lymphoid follicles might even be enlarged. Similarly, one often encountered simple smoothness and flatness of the base of the tongue, particularly in elderly, cachetic, or markedly anemic individuals, but the essential feature of smooth atrophy was lacking—that was, the induration due to connective tissue replacement. This suggested that in approaching the diagnosis both from the clinical and the anatomical standpoint the finger should be trained to appreciate the sense of resistance offered by the base of the tongue, and the sense of sight used only as an adjunct to that of touch. At the same time it was to be recalled that two types of smooth atrophy were capable of differentiation by the naked eye, one diffuse and characterized by induration and smoothness, the other patchy or insular in distribution and characterized by the presence of indurated, retracted scars. The former appeared to be far the more frequent type. It was of interest to note that in the microscopical examination of a number of atrophic tongues stained for spirochetes by Levaditi's older method their presence could not be detected.

Aplastic Anemia: Report of a Case with Exhibition of Pathological Specimens.—Dr. Joseph Charles Roper reported the case of an Italian who came to the hospital with the history of having been a little paler than normal for one or two months. Four weeks before admission he had what was believed to be grippe. During the last two weeks he had had hemorrhages from the nose. He had several nose bleeds and each time the blood flowed profusely. He was extremely anemic, the skin and mucous membranes being very pale. The gums were swollen and bled easily. His temperature on admission was 100.6° F. and his pulse 100. The retina showed a number of recent hemorrhages. The interest in this case centered in the blood and in the fact that, while in the hospital, he was twice transfused. Throughout his stay in the hospital his blood showed a persistent leucopenia. The red blood cells varied between 700,000 and 1,500,000, excepting after transfusion. No abnormal cells could be found. The hemoglobin was varied from 15 per cent. to 30 per cent. The hemorrhages persisted until death despite two successful transfusions. At autopsy the bone marrow was found to be markedly fatty. Smears from it showed mostly red cells and lymphocytes and rarely an eosinophile cell. The lymph nodes were enlarged and bright red throughout the body.

The Cammidge Reaction: A Study of Its Value.—Dr. Roper said that by slightly modifying the Cammidge technique, he and Dr. Stillman were able to remove entirely the substance giving rise to the Cammidge crystals. This modification consisted in making all additions in the mortar and mixing by careful rubbing. Perfectly clear filtrates could always be obtained. In two cases in which all the crystals could not be removed because of their great quantity, a compound of glycerinic acid with parabromphynyl hydrazin was obtained with a specific melting point of 245°. Because of this and the fact that the Cammidge technique partly followed the regular procedure for the demonstration of glycerinic acid, they concluded that the reaction arising from glycerinic acid split off from its combination by boiling with hydrochloric acid and was not entirely removed by the lead acetate when not carefully mixed or present in a very large amount. The crystals, therefore, bore no necessary relation to pancreatic function.

Infant Feeding: Methods and Results.—Drs. Greenway and Rosenthal presented this communication. Charts were shown which demonstrated what had been done in the infant feeding classes at the New York Hospital, our-door department, during the summers of 1908 and 1909 There were two charts presented, one showing the control cases and the other the uncontrolled cases. The number of control cases that were breast fed, 84; number of months under observation, 272.5; average gain in weight per month, 1 pound, 15 ounces. Those fed on cow's milk numbered 25; number of months under observation, 70.9; average gain in weight per month, 1 pound, 11 ounces. The number of uncontrolled cases that were breast fed, 26; number of months under observation, 84.3; average gain in weight per month, 15.2 ounces. Those fed on cow's milk numbered 17; number of months under observation, 34.3; average gain in weight per pound, 7.6 ounces. Certain facts were to be deduced from these tables, and one was that the mothers in a greater number of instances nursed their children and that these children got along very well without any supervision on the part of the doctor or district nurse, and if anything was to be done in infant feeding, even with the limited means and facilities at hand, one should look after those babies that were fed on cow's milk.

Disturbances of Respiration: Graphic Studies.—Dr. Lewis A. Conner discussed this subject and illustrated his remarks with lantern slides. He said he had been studying the abnormalities of respiration by means of graphic tracings and he wished to show what he had been trying to do. The technique employed was a fairly definite one. He said one should distinguish sharply between the upper thoracic movement and lower thoracic and diaphragmatic movements. These represented two quite distinct respiratory systems, with separate centers of innervation, whose movements were to some extent independent of each other. He used two pneumographs, one for use over the upper part of the thorax, and the other for use over the epigastrium between the ensiform and the umbilicus. The type of pneumograph used by him and which seemed very satisfactory was the ordinary simple spiral spring pneumograph. Tracings taken from the upper thorax and the

epigastric region in various pathological conditions were then projected upon the screen.

Report of Standing Committee.—This committee was appointed to investigate the "Symptom Complex," as reported by Dr. Nathan E. Brill at the January meeting in his communication on "Pseudo-Typhoid Fever, a Clinical Study." At this meeting further reports were made on Dr. Brill's communication and several cases were reported. All of these were seen by several members of the committee. This committee was composed of Dr. John A. Fordyce, chairman; Dr. S. Lustgarten, Dr. W. Gilman Thompson, Dr. Warren Coleman, Dr. Theodore C. Janeway, Dr. Morris Manges, and Dr. E. Libman.

An Analysis of Twenty Cases Belonging to the Unclassified Group of Affections Clinically Resembling Typhoid Fever.—Dr. H. F. L. Ziegel said that so far as he knew Dr. N. E. Brill was the only observer who, for ten years or more, had made a systematic and careful study, together with agglutination reactions and blood cultures, of the group of affections which clinically more or less resembled typhoid fever, but etiologically and pathologically appeared to constitute at least one distinct entity. As a pupil of Dr. Brill's while an interne, he became greatly interested in these studies. The discussion, or rather argument, which followed Dr. Brill's discourse at the January meeting of this section seemed to hinge upon a mere difference in viewpoint, the participants having failed to define beforehand the terms they were using. Though applied to one of the most protean of diseases, even the term typhoid fever had limits of elasticity. Usually the practical clinician demanded the presence of the cardinal signs, namely, more or less prolonged temperature elevation, true roseola, the palpable spleen, etc., since cases with one or more of these signs absent which could be bacteriologically proved to be typhoid fever were rare, *e. g.* nonfebrile typhoid fever. Again, from a bacteriological side, there was demanded either a positive Widal reaction or a positive blood culture. Now, if in a very large number of cases, such as Dr. Brill had reported, the true roseola was regularly absent and the Widal reaction and blood culture were reguarly negative, they were certainly justified in concluding that the great majority of these cases, to say the least, were not typhoid fever. The negative evidence might, therefore, be very valuable. Stimulated by Dr. Brill's work, Dr. Siegel undertook at the Beth Israel Hospital to collect and study the near-typhoid cases which had been treated in the hospital during the past two and a half years. The following was the result of his analysis of twenty cases which he had studied: The onset was sudden in sixteen of the cases, gradual in four. The average duration of the symptoms before admission was 6.8 days. The common symptoms were chilliness, headache, prostration, anorexia, and constipation; the less common symptoms were abdominal pain in four cases, epistaxis in three cases, diarrhea in two cases, and vomiting in one case. As to the febrile period, estimated from the anamnestic inception to complete defervescence, the longest was twenty days, the shortest was eight days, and the average was 12.2 days. As to the time of actually observed temperature elevation in the hospital, the longest was ten days, the shortest was three days, and the average was 5.3 days. The fall in the temperature was very rapid in nearly all the cases, reaching normal in from twelve to twenty-four hours, and then never rising above normal. The spleen was palpably enlarged in seventeen of the cases. As to the skin eruption, in eight of the cases there was a diffuse maculopapular eruption on the chest and extremities, as well as on the abdomen; in four of these cases there were suspicious roseolæ in addition; in three of these cases there were suspicious roseolæ only, and in only one of the cases was the eruption judged to be truly roseolar. The Widal reaction was performed in every case and was regularly negative; in six of the cases it was negative three times, in two of the cases four times, and in one of the cases five times. In the four cases in which blood cultures were made, they were all negative. Leucocyte counts were made in all of the cases and showed practically normal counts in 75 per cent. of the cases, and a well-marked leucopenia in 25 per cent. of the cases. There were no complications. There were no cases with abdominal distension. There were no recrudescences, relapses, or fatalities.

Dr. Warren Coleman reported that since the last meeting four cases, similar to those described by Dr. Brill, had entered Bellevue Hospital, two of them into his service. Dr. Brill had seen the patients and had agreed in the diagnosis. All of the patients had come from the same family—father, mother, daughter, and a relative living with them. This fact was contrary to Dr. Brill's experience that the disease did not appear to possess epidemic characters. Three of the patients had very mild attacks, the fourth was very ill. None of the patients presented symptoms materially different from the description given by Dr. Brill. However, the patient who was severely ill gave marked evidences of meningismus, stiffness of the neck, Kernig's sign, and muscular twitching. Sixty c.c. of clear spinal fluid were obtained, under pressure. Four blood cultures had been taken from this patient, and bacteriological examinations of the spinal fluid, of the stools, and of the urine had been made with negative results. Daily tests of the serum against several strains of the typhoid bacillus, of the intermediates, and of the colon bacillus had been carried out, also with negative results. Similar, but less frequent, examinations had been made in the second case, all of which had likewise proved negative. Dr. Coleman felt, however, that these various examinations had not been sufficiently complete, especially the serum tests, to make it possible to draw any conclusions respecting the nature of the infection, and stated that this was simply a report of progress.

Stated Meeting, Held March 15, 1910.

Dr. C. N. B. Camac in the Chair.

Paralysis of Extraocular Muscles in Exophthalmic Goiter.—Dr. Linsey R. Williams presented this patient, a German, fifty-five years old, a machinist. A sister had a goiter. In July, 1909, he began to see double, and then his eyes became prominent. In November he had to stop work because of the condition of his eyes. He grew very nervous and irritable and lost weight. There was slight cardiac hypertrophy, irregular action, and a systolic apical murmur. There was a tremor of the head at times. The thyroid was slightly enlarged. The exophthalmos was marked. There was a retraction of both orbicularis palpebrarum muscles, causing a widening of the palpebral fissure. The eyelids did not follow the eye movements downward. There was a paralysis of the superior rectus and oblique muscles, and a paresis of the external rectus on the right side; on the left side there was a paralysis of the superior rectus and oblique and inferior oblique muscles and a paresis of the external rectus muscle. Möbius' sign, due to fatty infiltration and insufficiency of the internal rectus, was present. In this case the diagnosis of exophthalmic goiter seemed plausible, although all the cardiac symptoms were not present.

Nephritis; Edema and Uremia for Eight Months; Recovery.—Dr. Theodore C. Janeway presented this patient. Her father died of kidney disease, and a sister died of tuberculosis. She had measles and mumps when a child. Her habits were good. One year be-

fore her admission she had attacks of nausea and vomiting once or twice a month. Six months before admission her ankles and legs became edematous, and four months before admission a double Edebohl's operation was performed. After this she had increasing headaches, dyspnea, palpitation and oppression, pallor, edema of eyelids, ascites, and failure of vision. She came into the hospital because of vomiting, headaches, and edema of the eyelids. One week before her admission she had a convulsion. The physical examination showed a woman well nourished, pale, with considerable edema of the face and eyelids, legs, thighs, and of the abdominal walls. The pupils were normal. There were moist râles in both lungs. She had an acute retinitis, a neuritis of the optic nerve, as well as edema of the retina. The abdomen was aspirated several times. She was given hot packs, a fluid diet, chloral, and glonoin. For the relief of her headaches, morphine had to be given, which relieved her. To-day she looked the picture of health, although there was still a small amount of albumin in the urine, and she urinated quite frequently. The case was of interest because the edema and uremia, lasting eight months, were followed by complete recovery.

The Treatment of Typhoid Fever with Vaccines.—Dr. Austin W. Hollis made this report. A review of the literature showed that the treatment was still in the experimental stage, with doses ranging from 1,000,000 to 300,000,000 dead typhoid bacilli, and no uniformity as to the repetition of the dose. In the cases reported the dose was given subcutaneously in the region of the buttocks, every second or third day, each dose being either ten or fifty million dead bacilli During the summer and fall they had 37 cases of typhoid fever; 21 cases were treated by the older methods of hydrotherapy, either by the tub bath or sponging; 11 were treated with vaccine without hydrotherapy; the remaining five were too short a time under treatment to make any comparisons. The diet in general was of the high caloric variety. No drugs were employed, but strychnine and whisky were used as stimulants in the severe cases. The bowels were moved by enemata. The patients who were treated by vaccination received no baths other than a daily warm soap and water sponge. In a very few cases 250,000,000 bacilli were employed, but no different clinical or laboratory effect could be noticed between the smaller and larger doses. No case ended by crisis. The agglutinins were markedly stimulated by the vaccines. The average day of admission from the beginning of the first symptom was 11.3 and 13.8; of defervescence 36.7 and 34.3 for the vaccination and hydrotherapy cases respectively. The temperatures ranged high in both series. Hemorrhages were seen with equal frequency, although not so severe in the vaccination cases. Relapses were noted with more frequency in the vaccinated cases, 30 per cent. as compared with 10 per cent. The cases receiving the vaccine were in no way selected. No death occurred in the vaccinated cases; four occurred in the other series, one from hemorrhage, one from toxemia, one from perforation, and one from pulmonary thrombosis with necrosis of the whole left upper lobe of the lung. Headache, gastrointestinal symptoms, and toxemia were far less frequent in the vaccinated cases; the absence of discomfort seemed striking, while convalescence was more rapid. Dr. Hollis said that it would be absurd to assume any positive value from vaccine therapy in typhoid fever in such a small series of cases, yet from theory alone he predicted a brilliant future for typhoid vaccine as a protective as well as a therapeutic agent.

Serumtherapy in Purpura Hæmorrhagica.—Dr. F. Morris Class said that, in view of the increasing interest in serum therapy, and because it had been advocated mainly in hemophilia, it seemed justifiable to report a case. The patient was an adult woman who entered St. Luke's Hospital May 11, 1908, and who was in the service of Dr. Theodore C. Janeway. Her chief complaint was pain in the region of the bladder, and hemorrhages under the skin. Ten years ago she had profuse bleeding from the gums, which were spongy and purple. Later petechial spots appeared on the body. At times she had had "bruises" on the body, for which she could not account. Three days before her admission the wrist of the right side became swollen, painful, and a hemorrhagic spot appeared over the head of the ulna. She had chilly sensations, fever, and crops of petechial spots on various parts. The pain disappeared in thirty-six hours, except for some burning and aching in the bladder region. This had persisted until the present and was not influenced by urination. The urine looked to the patient as though it contained blood. The patient was prostrated and acutely ill. The lower part of the abdomen was protruberant and tender to pressure. The bladder was enormously distended. Both kidneys were tender. Other organs appeared to be normal. There were hemorrhagic spots on the skin varying in size from petechiæ to the diameter of a centimeter or more, and covered a large part of the chest and abdomen. About the elbows, wrists, and ankles were diffuse hemorrhagic areas, 8-10 cm. in diameter. Small hemorrhagic patches were on other parts of the body. The eye grounds showed no hemorrhages. On admission her temperature was 101.3°, pulse 104, and respiration 24. The red cells numbered 3,468,000; the hemoglobin was 75 per cent.; the white cells numbered 5,500; the polymorphonuclears were 64 per cent., and lymphocytes 36 per cent. Hyaline and granular casts and blood were found in the urine. The patient was given an amount equal to 5,000 units of antidiphtheritic serum and calcium lactate. On May 17 (six days later) it was noted that the old hemorrhages were disappearing and no new ones were seen. She was given 6,400 units of the same serum and the calcium lactate was stopped. On May 25 the urine and stools were negative for blood, the improvement was steady, and convalescence seemed established. On June 30 she was nauseated and vomited. There were several small ecchymotic spots on the legs, the stools were fluid and black and contained blood. The temperature rose to 102.3°. She was given 10 c.c. fresh horse serum subcutaneously. On July 12 the urine and stools appeared normal and the patient seemed wholly to have recovered. Eight months after leaving the hospital she was enjoying perfect health.

Trichinosis:. Demonstration of Trichinæ Occurring in the Blood and Muscle Simultaneously.—Dr. Edward W. Packard reported such a case and demonstrated the blood and muscle findings by means of the lantern.

Obscure Cases of Leukemia.—Dr. Francis C. Wood reported three such cases that he had seen at St. Luke's Hospital which were very interesting from the point of diagnosis. He pointed out some of the difficulties encountered in endeavoring to classify the irregular types of leukemia. The blood was thoroughly studied and he had found a large number of types of what might be called leukemia, but did not correspond to the textbook pictures.

Pneumoperitoneum with a Means of Diagnosis.—Dr. William Herrick said that the physical evidence of pneumoperitoneum was an obliteration of liver dullness.

He had made several observations on dogs and on cadavers. A method of diagnosis he presented consisted in the employment of an ordinary wash bottle in which a partial vacuum had been made. A needle with a blunt point and lateral openings was attached by means of rubber tubing to the bottle. When the needle was passed into the peritoneal cavity the presence of gas was demonstrated by the bubbles in the liquid in the bottle. When lead acetate was in the solution the formation of the black sulphide of lead showed the presence of sulphuretted hydrogen, and, therefore, the gas was of intestinal origin. This was the most delicate and absolute sign of free gas in the peritoneal space, but care should be exercised to exclude gas of intestinal origin.

Dr. HENRY W. BERG believed there was a certain amount of danger in the use of such an instrument used for diagnosis on the human being. It was not such a difficult matter to differentiate free gas in the peritoneal cavity or tympanitic distention. If the latter condition was present there would be a disappearance of liver dullness from below upwards; but if there was free gas in the peritoneal cavity as from a perforation, then there would be a disappearance of liver dullness from above downward or a concentric disappearance of liver dullness.

Intravascular Phagocytosis of Red Cells.—Dr. J. G. HOPKINS reported the case of a patient with a severe form of progressive anemia, with persistent and severe diarrhea. The blood findings were illustrated with lantern slides.

Experiments on the Value of Alkali Therapy in Gout.—Dr. HERMAN O. MOSENTHAL made this laboratory report. He said that alkalis are often administered to gouty patients in order to render the blood and urine more alkaline and thus increase the power of these fluids to dissolve uric acid and excrete it. There were many objections to the theory that underlay this method of treatment. In putting the alkalis to a practical test, it had been noted that an acute paroxysm was often precipitated in the gouty sufferer by an administration of alkalis. It had sometimes been claimed that herein lay the principal advantage of this treatment, since during the acute attack much of the retained uric acid was thrown out in the urine.

In determining the effect of sodium bicarbonate on dogs, it appeared that the uric acid excretion was uninfluenced if the nitrogen metabolism were on a low plane. When, however, meat was added to the diet in considerable amounts the bicarbonate of soda resulted in a marked diminution in the output of uric acid. There was no compensatory rise in the after period. The metabolism in the latter instance was comparable to that in a gouty patient. In both cases there was a large amount of uric acid present in the system. The bicarbonate of soda diminished its excretion and made a greater demand on the uricolytic powers of the organism. The pathological processes of metabolism in gout were not equal to these conditions, with the result that uric acid accumulated in the system and finally gave rise to an acute paroxysm.

Pain.—Spalding divides the causes of pain into, first, chemical, which may be either internal or external, as lead poisoning and the effects of an acid; second, mechanical, including friction, pressure, traumatism, bending and stretching.—*Memphis Medical Monthly.*

Havana Slaughter Houses.—Ruiz Casabé reviews the slaughter houses of Havana and describes the barbarous, almost primitive methods employed in two of the three principal slaughter houses. In all but one of them there is complete absence of not only sanitary requirements, but of proper humanitary methods as well.—*Crónica-Medico-Quirurgica de la Habana.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MEDICAL EXAMINING BOARD OF NORTH DAKOTA.

January, 1910.

ANATOMY.

1. Name the divisions of the ear and the contents of the tympanum.
2. Describe the male urethra.
3. What nerves form the brachial plexus?
4. Name all the muscles moving the arm.
5. Describe the elbow joint.
6. Describe the popliteal space; gave its boundaries and contents.
7. Describe the axillary artery.
8. With what bones does the fibula articulate?

HISTOLOGY.

1. Give the distribution and structure of nonstriated muscle.
2. Describe the lining of the stomach.
3. Give the histology of the gall-bladder and ducts.
4. Name and describe the different kinds of epithelium.
5. Give the histology of a medium-sized artery.

PHYSIOLOGY.

1. Describe the function of the heart.
2. Define: (*a*) proteids; (*b*) carbohydrates, and name an example of each.
3. Describe the process of digestion of an egg sandwich.
4. Describe carefully normal urine.
5. What structures possess the function of: (*a*) elimination; (*b*) secretion?

MATERIA MEDICA.

1. What is meant by incompatibility? Distinguish between chemical and physiological incompatibility.
2. Define diuretic and diaphoretic, and name three drugs belonging to each class.
3. What is an anthelmintic. Give names of three.
4. Give physiological action of strophanthus, the dose of the tincture, and indications for its use.
5. Give dose of the following drugs: (1) morphine sulphate; (2) atropine sulphate; (3) apomorphine hydrochlorate; (4) Dover's powder; (5) phenacetin; (6) tincture of opium; (7) oleum tiglii; (8) oleum terebinthinæ; (9) pilocarpine nitrate.

CHEMISTRY AND TOXICOLOGY.

1. Describe a chemical test for detection of organic impurities in drinking water.
2. Give formula and explain difference between corrosive mercuric chloride and mild mercurous chloride of the pharmacopœia.
3. Give a chemical test for hydrochloric acid in stomach contents.
4. Describe methyl and ethyl alcohol.
5. $AgNO_3 + NaCl = ?$
6. What is an antidote for poisoning by corrosive sublimate?
7. Give symptoms and treatment of arsenical poisoning.
8. Differentiate between alcoholic and opium coma.

PATHOLOGY.

1. (*a*) What are the causes of fever? (*b*) What are the effects of fever?
2. (*a*) Mention all the pathological conditions which may produce hemoptysis. (*b*) The same of hematemesis.
3. Give the pathology of tubercle.
4. Explain the propagation of tapeworm.
5. Mention the different varieties of goiter and give their pathological differences.

PRACTICE.

1. How diagnose typhoid fever?
2. Give differential diagnosis between smallpox and chickenpox.
3. Discuss the treatment of pulmonary tuberculosis among the poor.
4. Give treatment for the two most common of the valvular heart lesions.
5. Give treatment for the different pleural effusions.
6. Discuss prognoses in cerebral embolism and cerebral hemorrhage.
7. Write a short article on epilepsy.
8. Discuss intestinal neurosis.

9. How would you manage a case of nervous prostration in a very poor family?
10. What are the comparative urinary findings in the first stages of chronic parenchymatous and chronic interstitial nephritis?

NERVOUS DISEASES.

1. Give diagnosis and treatment of infantile paralysis.
2. Diagnosis of cerebral tumor.
3. Name five reflexes and manner of detecting them.
4. Diagnosis and treatment of chorea.
5. Diagnosis and treatment of tuberculous meningitis.

OBSTETRICS.

1. Diagnosis of pregnancy at three months; at six months, and number of days in which it terminates at full term.
2. Name and describe the various head presentations.
3. How would you proceed in a case of placenta previa?
4. What are the dangers of prolapsus of the cord, and how would you treat it?
5. Give the causes for asphyxiation of the infant, and your method of overcoming it.
6. How treat a case of puerperal sepsis?

DISEASES OF WOMEN AND CHILDREN.

1. Give cause, symptoms, diagnosis, prognosis, and pathology of pyosalpinx.
2. Mention some of the causes of sterility in women, and outline treatment.
3. Differentiate between tubal pregnancy, pyosalpinx, ovarian cyst, and appendicitis.
4. Describe the uterus and its changes during pregnancy.
5. Give causes and treatment of rectovaginal fistula.
6. Describe and give cause for "Hutchinson's teeth."
7. In what class of subjects are the cells sensitized to diphtheria antitoxin, making its administration almost sure to cause sudden death?
8. Give symptoms, diagnosis, and treatment of intussusception in a boy twelve years of age.
9. Give symptoms, pathology, and treatment of Pott's disease of the spine.
10. How do you make a positive diagnosis of diphtheria?

SURGERY.

1. Give diagnosis, prognosis, and treatment of fracture at the neck of femur.
2. Give indications for trachelorrhaphy. Describe the operation.
3. Give causes and treatment of retention of urine.
4. How do you treat punctured wounds?
5. How do you select and administer a general anesthetic?
6. Give diagnosis and treatment of strangulated inguinal hernia.
7. Give diagnosis and surgical treatment of gall-stones; describe the operation in detail.
8. Give diagnosis and treatment of the different dislocations of the shoulder.
9. What is a Colles fracture? How do you dress it?

EYE AND EAR.

1. Cause, symptoms, and treatment of ophthalmia neonatorum.
2. Causes, symptoms, and treatment of iritis.
3. Causes, symptoms, and treatment of glaucoma.
4. Treatment of blepharitis marginalis.
5. Define astigmatism, myopia, hypermetropia, diplopia, and chalazion.
6. Treatment of acute otitis media.
7. Symptoms and treatment of acute mastoiditis.
8. How do you remove foreign bodies from the ear?
9. How relieve pain in furunculosis of the auditory canal?
10. Describe fully effect of nasopharyngeal adenoids upon the ear and its function.

MEDICAL JURISPRUDENCE.

1. What is a malingerer, and how would you set about to discover whether a patient were feigning sickness or not?
2. Within what period after the treatment complained of can a patient maintain an action for malpractice against a physician or surgeon in this State?
3. (*a*) Does the law of this State fix a schedule of fees limiting charges of physicians and surgeons either for traveling to attend patients professionally, or for professional services rendered, and if so, what is it? (*b*) What, if any, preference is given by the statutes of this State to physicians and surgeons in the matter of collection of their fees for professional services rendered their patients?
4. Does the law of this State fix any definite minimum period of gestation in civil or criminal matters in the courts of the State involving the determination of paternity, and if so, what is it?
5. A duly licensed physician and surgeon in this State is called upon by a female who complains of symptoms which indicate ovarian trouble. The doctor diagnoses the case as one of infected cyst of the ovary, and advises that an immediate operation is necessary. The patient consents, and the doctor operates and finds the trouble to be that diagnosed. He successfully removes the cyst, but in doing so accidentally incised the intestine. While he undertook to repair the unnecessary incision in the intestines, he nevertheless failed, and the woman died. Is he liable to action for malpractice, and if so, why?
6. Has the State Board of Medical Examiners power, under the laws of this State, to reinstate a physician and surgeon in good standing and reissue a license to him to practise medicine and surgery in the State, after their former license to him has been revoked for the commission of a felony of which he has been convicted in this State?

PREVENTIVE MEDICINE.

1. If treating a case of typhoid in the country, give your instructions in full to family regarding the prevention of spread of the disease.
2. Name all the ways you know in which tuberculosis may be communicated, and what would be your method of preventing the same?
3. Give your method of fumigating for smallpox.
4. Describe the different methods of obtaining a pure water supply for a prairie town of 2,500.
5. Name all the diseases you know of that need quarantine and length of time required in each case.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

MEDICAL EXAMINING BOARD OF NORTH DAKOTA.

January, 1910.

ANATOMY.

1. External ear, middle ear, or tympanum; and internal ear or labyrinth. For contents of tympanum see Cunningham's "Anatomy" (1909), page 748; or Gray's "Anatomy" (1908), page 1160.
2. See Cunningham's "Anatomy" (1909), page 1177; or Gray's "Anatomy" (1908), page 1450.
3. The anterior divisions of the fifth, sixth, seventh, and eighth cervical, and the first dorsal nerve.
4. See Cunningham's "Anatomy" (1909), page 331; or Gray's "Anatomy" (1908), page 308.
5. See Cunningham's "Anatomy" (1909), page 279; or Gray's "Anatomy" (1908), page 310.
6. See Gray's "Anatomy" (1908), page 707.
7. See Cunningham's "Anatomy" (1909), page 827; or Gray's "Anatomy" (1908), page 649.
8. Tibia and astragalus.

HISTOLOGY.

1. In *nonstriated muscle* "the individual fibers are short, narrow, and spindle-shaped. Each is usually 25 to 200 microns in length, and 5 to 70 microns in breadth. No sarcolemma is present, and striations are absent. In each fiber there is but one nucleus, which is long, slender, darkly staining, and centrally located. This is not seen in all cross-sections, but when present shows as a small, dark dot. These fibers vary in length from 25 to 200 microns, ordinarily; in diameter they average about 5 microns. The fibers are arranged in bundles, but instead of forming masses like muscles the bundles are arranged into layers, which extend circularly and longitudinally in the hollow viscera. Capillaries exist between the fibers. The *nerves* are chiefly of the *sympathetic* variety. *Distribution:* Involuntary muscles are found in the alimentary tract from the middle third of the esophagus to the anus, in the ducts of glands, in the trachea and bronchial tubes, the internal urinary and genital systems, circulatory (except the heart) and lymphatic systems, and the capsules of some organs."—(From *Radasch's Compend.*)
2. See Cunningham's "Anatomy" (1909), page 1059; or Gray's "Anatomy" (1908), page 1283.
3. See Cunningham's "Anatomy" (1909), page 1119; or Gray's "Anatomy" (1908), page 1352.
4. KINDS OF EPITHELIUM. (1) *Pavement* or *Squamous:*

A single layer of flat, nucleated cells, cemented together at their edges. (2) *Stratified:* In layers of cells that are unlike in form. (3) *Columnar:* Tall, cylindrical cells arranged in a single layer. (4) *Cuboidal:* Similar to columnar, but the cells are shorter. (5) *Ciliated:* Columnar cells with hair-like processes (cilia) on their free surface. (6) *Goblet:* Cylindrical cells distended with mucin. (7) *Transitional:* When the cells are neither arranged in a single layer like squamous, nor yet in many superimposed layers like stratified, but in two or three layers.

5. See Cunningham's "Anatomy" (1909), page 781; or Gray's "Anatomy" (1908), page 587.

PHYSIOLOGY.

1. The function of the heart is to propel the blood through the blood-vessels. The *cardiac cycle* includes all the changes which occur between the commencement of one heart-beat and the commencement of the next; it consists of the alternate contractions (or systole) and relaxations (or diastole) of the auricles and ventricles of the heart. The contraction of the two auricles takes place simultaneously and is followed by the simultaneous contraction of the two ventricles; then follows a period during which the whole heart is in a state of diastole. The cycle then begins again with the auricular systole.

2. (*a*) *Proteids* are highly complex compounds of unknown constitution, whose molecule contains carbon, hydrogen, oxygen, nitrogen, and sulphur, and sometimes other elements, and occurring in nearly all parts of the body. *Example:* Albumin.

(*b*) *Carbohydrates* are compounds consisting of carbon, hydrogen, and oxygen, the last two being in the proportion to form water; most of the simple carbohydrates are aldehydes or ketones. *Example:* Sugar.

3. The *egg* consists of: Proteid and fat. *Bread* consists of carbohydrate, proteids, and fat. *Butter* consists of fat and proteids. Of these, the *proteids* are digested in the stomach by the pepsin of the gastric juice, and in the small intestine by the trypsin of the pancreatic juice. The *carbohydrates* are digested (slightly) by the ptyalin of the saliva and mainly in the small intestine by the amylopsin of the pancreatic juice. The *fat* is digested in the small intestine by the steapsin of the pancreatic juice.

4. *Normal urine* is a yellowish fluid secreted by the kidneys to the amount of about 1200-1500 c.c. daily; specific gravity, about 1015 to 1025; acid reaction (due to acid sodium phosphate); it has a characteristic odor and a salty taste. Its normal constituents are: Water, urea, uric acid, urates, hippuric acid, kreatin, kreatinin, xanthin, hypoxanthin; sulphates, chlorides, and phosphates of sodium and potassium; phosphates of magnesium and calcium; nitrogen, and carbon dioxide.

5. (*a*) *Structures of elimination:* Lungs, kidneys, intestines, skin. (*b*) *Structures of secretion:* Serous and synovial membranes; mucous membranes (glands in mouth, stomach, and intestines); salivary glands and pancreas; liver; mammary glands; lacrimal glands; kidneys; skin; testes.

MATERIA MEDICA.

1. By *incompatibility* is understood the simultaneous administration or combination of substances not suitable for such combination. *Physiological incompatibility* occurs when two remedies are thus administered which offset each other's physiological action, so that they are inert. *Chemical incompatibility* occurs when remedies which are mixed together undergo chemical decomposition or explosion.

2. *Diuretics* are agents which promote the secretion of urine. Examples: water, alcohol, potassium acetate.

Diaphoretics are agents which promote the secretion of sweat and increase the activity of the skin. Examples: alcohol, Dover's powder, Turkish bath.

3. *Anthelmintics* are agents which kill or expel worms. Examples: Oleoresina aspidii, gr. xxx; Pelletièrine tannate, gr. x; santonin, gr. j; pumpkin (pepo) seeds, ℥j.

4. *Strophanthus* causes stiffness of limbs and loss of voluntary movement; it paralyzes the muscles; it stimulates the heart, prolongs diastole, increases the force of the cardiac contractions, lowers and regulates cardiac rhythm, and raises blood pressure; it is a diuretic. The dose of the tincture is ♏viij. It is used like digitalis in mitral diseases, aortic stenosis, tricuspid diseases, cardiac dilatation, exophthalmic goiter, chronic alcoholism, nephritis, palpitation of the heart.

5. *Dose* of: (1) Morphine sulphate, is gr. ¼. (2) Atropine sulphate, gr. 1/160. (3) Apomorphine hydrochloride, gr. 1/10. (4) Dover's powder, gr. vijss. (5) Phenacetin, gr. vijss. (6) Tincture of opium, ♏viij. (7) Oleum tiglii, ♏j. (8) Oleum terebinthinæ rectificatum, ♏xv. (9) Pilocarpine nitrate, gr. 1/5.

CHEMISTRY AND TOXICOLOGY.

1. Organic matter in drinking water can ordinarily be detected by the addition of solution of potassium permanganate, which becomes rapidly discolored in the presence of the former.

2. *Corrosive mercuric chloride*, $HgCl_2$. Corrosive sublimate is heavy, white, and crystalline; it has a strong, acrid, styptic taste, and is soluble in water, in alcohol, and in ether; it is decomposed by exposure to light.

Mild mercurous chloride, Hg_2Cl_2, calomel, is a heavy, white powder, amorphous, tasteless, and odorless; it is insoluble in cold water and in alcohol, and very slightly soluble in boiling water; when exposed to the light it becomes discolored (first yellow, then gray) and partially decomposed; it sublimes without fusing.

3. *Test for free hydrochloric acid in the gastric juice:* The best is probably the Dimethylamido-azobenzol test; the reagent is used in 0.5 per cent. alcoholic solution, of which one or two drops are added to a like amount of the filtered gastric juice. If free HCl is present, the yellow solution turns red.

4. *Methyl alcohol* is a colorless liquid having an ethereal and alcoholic odor and a sharp, burning taste; burns with a pale flame, giving less heat than that of ethylic alcohol; mixes with water, alcohol, and ether in all proportions; is a good solvent of resinous substances, and also dissolves sulphur, phosphorus, potash, and soda.

Ethyl alcohol is a thin, colorless, transparent liquid having a spirituous odor and a sharp, burning taste. It mixes with water in all proportions, the union being attended by elevation in temperature and contraction in volume (after cooling to the original temperature). It also attracts moisture from the air to such a degree that absolute alcohol only remains such for a very short time after its preparation.

5. $AgNO_3 + NaCl = AgCl + NaNO_3$.

6. White of egg in moderate quantity, followed by an emetic.

7. The *symptoms of acute arsenical poisoning:* "In acute cases the symptoms usually begin in from 20 to 45 minutes. Nausea and faintness. Violent, burning pain in the stomach, which becomes more and more intense, and increases on pressure. Persisting and distressing vomiting of matters, sometimes brown or gray, or streaked with blood, or green. Purging. More or less severe cramps in the lower extremities."—(Witthaus' *Essentials of Chemistry.*) The chemical antidote is freshly prepared ferric hydroxide. The ferric hydroxide changes the arsenic into ferrous arsenate, which is nonpoisonous.

8. In *opium coma:* The pupils are contracted, the respiration is slow and full, the skin warmer than in alcohol poisoning, the face suffused, and the pulse slow and full. In *alcohol coma:* The pupils are not contracted, the respiration approaches the normal, the skin is cool and sometimes moist, the face may be pallid, and the pulse is rapid.

PATHOLOGY.

1. (*a*) *Causes of fever:* Disturbance of the heat-regulating centers, either directly or by toxic substances circulating in the blood. These latter may come from bacteria, or may he due to disordered metabolism, or to chemical or mechanical injury of the tissues.

(*b*) *Effects of fever:* Loss of appetite, thirst, emaciation, disturbance of function, the alkalinity of the blood is lessened; degenerative changes such as cloudy swelling, fatty degeneration, and coagulation necrosis may occur in the tissues, particularly in the heart, liver, kidneys, and muscles.

2. (*a*) *The causes of Hemoptysis:* Traumatism; certain organic diseases of the lung, especially tuberculosis, lobar pneumonia, bronchiectasis, gangrene, infarct, and cancer. Passive congestion, the result of heart disease, especially mitral lesions; rupture of aortic aneurysm; diseases profoundly affecting the blood, such as purpura, hemophilia, scurvy, and leukemia; ulcers, traumatic, syphilitic, or malignant of the trachea or larynx; and vicarious menstruation (very rare).

(*b*) *The causes of Hematemesis:* Traumatism; gastric ulcer; gastric cancer; venous engorgement of the stomach following cirrhosis of the liver, primary splenomegaly, or chronic heart disease; acute gastritis; blood dyscrasia, as in scurvy, purpura, severe infections, and grave anemias; rupture of aneurysm; swallowing of blood from nose, mouth, or throat; vicarious menstruation; hysteria.—(From Stevens' *Proctice.*)

3. See French's "Practice" (1907), page 342; or Osler's "Practice" (1909), page 295.

4. The cycle of the adult tapeworm is as follows: "From each individual segment, which is possessed of a complete reproductive system, great numbers of eggs are discharged. The latter are expelled from the intestine with the feces, and some of them may eventually enter the digestive tract of swine or cattle through the food or water. In the intestine the embryos become liberated from the eggs, and they then make their way in large numbers to the muscular tissue, brain, liver, and other parts, where they come to rest and develop as bladder worms. The living animal shows nothing in its appearance to indicate the presence of the parasite, excepting when the cyst can be seen in the under side of the tongue or between the tongue and the lower jaw. If now the animal is slaughtered and the meat eaten raw or imperfectly cooked, the cysticercus is freed from its enveloping capsule and proceeds to develop into an adult tapeworm, and the cycle is complete."—(From Harrington's *Hygiene.*)

5. See French's "Practice" (1907), pages 546 and 548; or Osler's "Practice" (1909), pages 763 and 765.

PRACTICE.

1. See French's "Practice" (1907), page 101; or Osler's "Practice" (1909), page 93.

2. (1) Very young children are attacked with varicella, whereas variola usually shows itself in adults. (2) Vaccinated children readily take varicella; not so variola, even in the modified form. (3) Children who have had varicella may contract variola, even soon afterwards; or the two diseases may coexist. (4) Varicella is noninoculable, whereas variola is notoriously so. (5) The eruption of varicella appears in 24 hours; that of variola not till the third day. (6) The febrile symptoms continue after the eruption appears in varicella; those of variola subside. (7) In varicella the spots come out in excessive crops; this is never seen in variola. (8) The spots in varicella are unilocular, and collapse on being punctured; the spots in variola are multilocular, and do not collapse on being punctured. (9) In varicella the eruption is very irregular, and appears over the body generally; in variola it appears in groups of threes and fives, and is always seen on the limbs. (10) The papule in varicella is soft, and disappears on stretching the skin; in variola it is hard and shotty, and does not disappear on stretching the skin.—(From J. W. Moore's work on *Variola and Varicella.*)

4. See French's "Practice" (1907), page 592; or Osler's "Practice" (1909), page 816.

5. See French's "Practice" (1907), page 699; or Osler's "Practice" (1909), page 653.

6. See French's "Practice" (1907), pages 1076, 1079, and 1082; or Osler's "Practice" (1909), pages 976 and 978.

7. See French's "Practice" (1907), page 1125; or Osler's "Practice" (1909), page 1058.

8. INTESTINAL NEUROSIS includes any disturbance of the motor, sensory, or secretory functions of the intestine, provided such disturbance is of nervous causation. (1) *Motor* includes: Paralysis of the intestines, disorders of defecation, constipation, intestinal obstruction, increased peristalsis, spasm, colic, tenesmus. (2) *Sensory* includes: Pain, colic, enteralgia. (3) *Secretory* includes: Nervous diarrhea, mucous colitis. For details of these see Index to French's or Osler's "Practice."

9. See French's "Practice" (1907), page 1153; or Osler's "Practice" (1909), page 1092.

10. In *chronic parenchymatous nephritis:* The urine is slightly diminished, turbid, has abundance of albumin, generally some blood, abundance of sediment, blood corpuscles, casts (especially fatty), diminished urea.

In *chronic interstitial nephritis:* The urine is increased in quantity, pale, clear, of low specific gravity, little or no albumin, scanty sediment, few casts, diminished urea.

NERVOUS DISEASES.

1. See French's "Practice" (1907), page 1084; or Osler's "Practice" (1909), page 916.

2. See French's "Practice" (1907), page 1104; or Osler's "Practice" (1909), page 991.

FIVE REFLEXES.	MODE OF EXCITATION.	NATURE OF RESULT.
Knee jerk.....	By striking patellar tendon with edge of hand or with percussion hammer, while leg hangs loosely over other leg.	A single upward jerk of the leg and foot, slight or distinct.
Ankle clonus.....	With knee extended or very slightly flexed, by pressing quickly and firmly against anterior part of sole of foot (so as to stretch calf-muscles) and then keeping up the pressure.	A series of clonic contractions at the ankle-joint, continuing as long as the pressure is maintained, and instantly ceasing when it is relaxed.
Plantar reflex.....	Tickling sole of foot.	Movements of toes; of these and foot; or of these and leg.
Gluteal reflex.....	Irritation of skin of buttock.	Contraction of glutei.
Cremasteric reflex.	Irritation of skin of upper and inner part of thigh.	Drawing up of testicle.

6. See Williams' "Obstetrics" (1909), page 883; or Hirst's "Obstetrics" (1909), page 737.

DISEASES OF WOMEN AND CHILDREN.

1. See Rose and Carless' "Surgery" (1908), page 1288.

2. The *most common causes of sterility in woman* are: Gonorrhea, absence or errors in development of any part of the genital tract, malformations of genitals, fistulæ, lacerations, obesity, alcoholism, pelvic inflammation, dyspareunia, inflammation of uterus, tubes, or ovaries, elongated cervix. *Treatment* consists in removing the cause, if possible; curettage has been recommended; in the presence of developmental errors little or nothing can be done; atresia of cervix can be treated by dilatation; if the uterus is misplaced it must be replaced.

3. In *extrauterine pregnancy,* there will be signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane or shreds, softening of the cervix, enlargement of the uterus, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden, excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage. In *appendicitis,* there are no signs of pregnancy; there are sudden pain and tenderness in the right iliac fossa, rigidity of right rectus muscle, fever, nausea, vomiting, constipation, no history of menstrual irregularities. In *pyosalpinx* the tubes are inflamed usually secondary to inflammation of uterus or to infection (either gonorrheal or puerperal), backache, pain in lower abdomen, history of menstrual irregularity, leucorrhea, tube is enlarged and tender. In *ovarian cyst,* no signs of pregnancy, the tumor may grow to enormous size, fluctuation generally distinct, emaciation, not painful, facies ovariana.

4. In the nulliparous adult the uterus is about three inches long, about two inches wide at the upper part, and about one inch thick. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments—broad ligaments, round ligaments, vesicouterine and rectouterine. *During pregnancy* the uterus increases in *size* (from 3 to 12 inches in length; from 1½ to 9 inches in breadth), in

weight (from about one ounce to two pounds, not including its contents). The cavity is enlarged over 500 times. All the tissues, muscles, ligaments, arteries, veins, lymphatics, and nerves become tremendously hypertrophied. The uterus also changes its position; at first it drops, later it gradually rises, till just before labor (when it again drops).

5. Rectovaginal Fistula. *Causes:* Protracted labor, ulceration due to pessaries or foreign bodies, carcinoma, syphilis or tuberculosis, pelvic abscess; it may be congenital. *Treatment:* A plastic operation is necessary. The edges of the fistula are denuded and then approximated with sutures, the same as for vesicovaginal fistula.

7. See Osler's "Practice" (1909), page 205.

8. See French's "Practice" (1907), page 804; or Osler's "Practice" (1909), page 525.

9. See Rose and Carless' "Surgery" (1908), page 718; or Da Costa's "Surgery" (1908), page 748.

10. By finding the Klebs-Loeffler bacilli.

SURGERY.

1. See Rose and Carless' "Surgery" (1908), page 535; or Da Costa's "Surgery" (1908), page 512.

2. Trachelorrhaphy. *Indications:* Laceration of cervix uteri; particularly when followed by subinvolution of uterus, by eversion and hypertrophy of cervix, by infection, by Nabothian-cysts, by menorrhagia, leucorrhea, backache, and reflex nervous disturbances.

Operation: "The patient is anesthetized and placed in the lithotomy position, and the cervix well exposed by a speculum. The vagina is thoroughly disinfected by douching and swabbing, and dilatation and curetting are then carried out when necessary. After this the anterior lip of the cervix is seized with a volsella, and the reversible tenacula forceps introduced exactly in the middle line and the points separated. The volsella is then removed. By means of scalpel and forceps two flaps are now dissected off the exposed surface, taking care to leave a narrow strip of mucous membrane in the middle line, which will form the lining for the new cervical canal when the lips are approximated. While the surfaces are being vivified there is usually free oozing; this is useful, as it serves to deplete the cervix and diminish its volume. In many cases before operation the bulky, everted lips look as if they could not come together, yet, after depletion brought about by dissection, they can be approximated with ease. When the flaps have been dissected off, the tenacula forceps are removed, the lips of the cervix are allowed to fall together, and the forceps are then reapplied in such a way as to hold them in apposition. Care must be taken to secure the cervix in the middle line. A curved needle is used to introduce the sutures; the best material is silkworm gut, and, if secured by means of shot and coil, their subsequent removal is greatly facilitated. Three or four sutures should be placed on each side, and those nearest the middle line should be about one centimeter apart. The tenacula forceps are now removed and a sound is passed into the uterus, to make sure that the cervical canal is free. The parts are then carefully dried, and the vagina lightly packed with iodoform gauze."

9. See Rose and Carless' "Surgery" (1908), pages 521 and 525; or Da Costa's "Surgery" (1908), pages 505 and 508.

EYE AND EAR.

1. Ophthalmia neonatorum. *Causes:* The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Symptoms:* Swollen eyelids, with copious purulent discharge; ulceration of the cornea may ensue. *Prophylaxis:* Whenever there is the possiblity of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. *Treatment:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of 2 per cent. solution of nitrate of silver must also be dropped onto the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

2. Iritis. *Causes:* Syphilis, rheumatism, gonorrhea, gout, diabetes, leprosy, scrofula, tuberculosis, injury, transmission from the other eye. *Symptoms:* Pain, photophobia, small pupil, ciliary congestion, discoloration of iris, exudate in anterior chamber. *Treatment:* Casual, abstraction of blood from temples, atropine, diaphoresis, shielding the eye from light.

3. Glaucoma. *Causes:* Increase of contents of eye, hypersecretion, retention, old age, gout, rheumatism, nephritis. *Symptoms:* Visual disturbances, increased ocular tension, hazy and anesthetic cornea, sluggish and dilated pupil, shallow anterior chamber, ciliary neuralgia, cupping of optic disc, blindness.

Treatment consists first in the local instillation of miotics, such as eserin or pilocarpin, to contract the pupil, and massage of the eyeball. Mydriatics are distinctly contraindicated. The operative treatment includes paracentesis, iridectomy, sclerotomy, and incision of the ligamentum pectinatum.

4. *Treatment of blepharitis marginalis:* Remove cause, if possible; remove scales, and keep edges of lids clean and fresh, warm water or weak boric acid solution, or bichloride of mercury 1:5,000; massage; silver nitrate (2 per cent.) on ulcers; epilation of distorted cilia; treat conjunctival or corneal disease.

5. *Astigmatism* is a condition in which, owng to a greater curvature of the eye in one meridian than in others, the refractive power of the eye varies.

Myopia is a condition in which the anteroposterior axis of the eye is abnormally long, and parallel rays are focused in front of the retina.

Hypermetropia is a condition in which the anteroposterior axis of the eye is abnormally short, and parallel rays are focused behind the retina.

Diplopia is a condition in which an object seen appears double.

Chalazion is a tumor in the eyelids, due to obstruction of the duct in a Meibomian gland.

6. *Treatment of acute otitis media:* "The treatment depends upon the symptoms, which are exceedingly variable. When the symptoms are those of middle ear-ache without great exudation, the treatment consists in the inflation of the Eustachian tube, alkaline spray to the post-nasal space, two to three drops of 8 per cent. solution of cocaine, dropped into the ear, and afterwards hermetically sealing the canal with small pledgets of cotton or inserting into the ear a few drops of the following, which will bring immediate results:

℞	Chloralis camphorat.,	5 parts.
	Glycerini,	30 "
	Ol. amygdalæ dulcis,	10 "

As soon as the pain has disappeared the hyperemia and swelling of the Eustachian tube is quickly reduced by spraying the post-nasal space with alkaline solution, followed by the application of argentum nitrate eight grains to the ounce. The treatment of the external auditory canal and tympanum consists in dropping three to four drops of solution of zinc sulphate, eight grains to the ounce, into the ear and hermetically sealing with collodion. This is repeated twice daily until all symptoms have passed away. If the pain and effusion into the ear is great, dry hot applications, paracentesis, purging, antipyretics, and rest in bed are indicated. The disease runs its course in from three to ten days."

7. Acute Mastoiditis. *Symptoms:* Tenderness, pain, swelling and redness over the mastoid; bulging of the superior and posterior parts of the auditory canal; temperature variable, from normal up to about 104° F. *Treatment:* Hot water, or cold water, or ice; leeches, purgatives; light diet; acetanilid, incision, or mastoid operation.

8. *Foreign bodies may be removed from ear:* (1) Insects, by warm water or chloroform oil; (2) by syringing carefully; (3) wax may be removed by disintegrating it with hydrogen dioxide, followed by warm water irrigation.

9. Leeches; hot applications of hops or salt; cleaning with hydrogen peroxide; morphine; evacuate pus.

10. "The presence of adenoid tissue in the vault of the pharynx affects the ear in two ways. If the mass is large by direct pressure upon the Eustachian orifice the supply of air in the tympanic cavity may be disturbed. . . . Any slight increase in the volume of the mass will close the lumen of the tube, after which the intratympanic air

is gradually absorbed by the blood which circulates through vessels in the walls of the cavity. With each act of swallowing, at which time the tube opens momentarily, the air is aspirated into the nasopharynx, the tube closing so quickly that the passage of air into the tympanum does not take place. In this manner a passive congestion of the mucous membrane of the middle ear is produced, a condition which constitutes practically the first stage of an inflammation, and, if long continued, results in permanent tissue changes. . . . The more important manner in which adenoid growths affect the organ of hearing is by the obstruction to the venous return current from the tympanum and labyrinth. The pharyngeal tonsil, in virtue of its presence, may exert sufficient pressure to partially obstruct the venous flow from the tympanic cavity. Any condition which affects, for a considerable period, the circulation within the middle ear will also cause a disturbance of the labyrinthine circulation from an alteration in the tension of the fluid contained. Such changes in the labyrinth render it particularly susceptible to inflammation, either as the result of infecton or of mechanical irritation, the most fruitful source of the latter being the crowding inward of the ossicular chain by atmospheric pressure, when the tension of air within the tympanum is reduced. . . . There may also be a diminution of bone conduction and a hyperesthetic condition of the auditory nerve." (From Dench's *Diseases of the Ear.*)

MEDICAL JURISPRUDENCE.

1. A *malingerer* is one who pretents to be ill when he is not. To aid in the discovery: Try to ascertain if there is any motive in such claim to be ill; make frequent and thorough examinations; the examiner should be well read and expert; instruments of precision and ancsthetics should be used if necessary; malingerers are apt to overdo their part.

2. As a rule, there is no statute of limitations fixing time within which an action for malpractice must be brought; but generally no such action will lie after a physician has brought suit for his fee.

3. (*a*) No. (*b*) None.

4. No.

5. If carelessness or negligence is proved, he is liable; but the matter will rest with the jury, and the verdict will depend largely on the "doctor on the other side," and the evidence of his "professional brethren."

6. No.

PREVENTIVE MEDICINE.

1. See French's "Practice" (1907), page 107; or Osler's "Practice" (1909), page 96.

2. See French's "Practice" (1907), pages 335 and 390; or Osler's "Practice" (1909), pages 287 and 351.

3. Fumigation should be by formaldehyde or sulphur. The best means of fumigating by formaldehyde gas are the following:

(1) By Trillat's apparatus, which "allows the solution of formalin to flow in a fine stream through a copper coil heated to redness by a flame beneath, and the gas and vapor passing directly into the room. The apparatus may be operated outside of a room, and the amount of gas liberated depends directly upon the strength and quantity of the solution evaporated.

(2) In Schering's method the solid paraform is heated in a receptacle over an alcohol lamp, and is especially valuable in disinfecting small rooms, closets, etc.

(3) The cheapest and most common form develops the gas directly by the oxidation of methyl alcohol, the vapors of the latter passing over or through tubes or coils of heated metal. The amount is uncertain and results indefinite." (Gould and Pyle's *Cyclopedia of Medicine and Surgery.*)

Formaldehyde gas is formed by the oxidation of methyl alcohol. The action is quicker and more certain if the temperature of the room is from 95° F. up to about 110° F.

4. *Water supply* from: (1) *Rain water* collected immediately as it falls as rain, dew, snow, etc. (2) *Surface water* collected in ponds, lakes, streams, etc., and in free contact with air. (3) *Ground water, or subsoil water*, derived from the rain water of the district, but which percolates through the subsoil, and so is not directly exposed to the atmosphere. (4) *Deep or artesian water*, which is separated from the ground water by one or more impermeable layers.

5. *Quarantinable diseases:* Cholera, yellow fever, smallpox, plague, typhus, leprosy, diphtheria, scarlet fever, measles, mumps, chicken pox, erysipelas. For *length of time*, see index to these diseases in French's or Osler's "Practice."

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of April 2, 1910.

	Cases	Deaths
Tuberculosis Pulmonalis	657	195
Diptheria	428	44
Measles	1,770	30
Scarlet Fever	726	30
Smallpox	—	—
Varicella	170	—
Typhoid Fever	35	6
Whooping Cough	27	9
Cerebrospinal Meningitis	7	3
Malarial Fever	—	—
Totals	3,820	317

The indication for the use of chloroform in obstetric practice will be greatly limited in the future, when its toxic effects upon the vital organs are better understood.—Stowe in *Surgery, Gynecology, and Obstetries.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended April 1, 1909:

THE ESSENTIALS OF THE PHYSIOLOGY AND PATHOLOGY OF DIGESTION*

BY ISAAC LEVIN, M.D.,

NEW YORK.

EVERY organized living being constantly loses substance and, consequently, needs some addition from the outside, in order to continue its life functions. A plant, through the aid of the chlorophyl (green) parts, is able to form its food synthetically from inorganic substances, water and air, from the latter of which it receives oxygen and carbon in the form of carbon dioxide. An animal, on the other hand, is unable to maintain its life on this simple material, is unable to build complex substances from it, and must receive for its food organic matter, which it splits up into less complicated molecules before it can assimilate it.

While the food of the different species of animals is varied to a very great extent, all these foodstuffs, on final analysis, are found to consist mainly of one of the three cardinal substances, protein, carbohydrates, or fats. Of these three the protein is the most important article of food. During its life functions, an organism creates a certain amount of energy which is lost either in the work of the different organs or in heat which the warm-blooded animals give off into their surroundings; and, on the other hand, it wastes a certain amout of body tissue which must be rebuilt. While both energy and heat can be created at the expense of the carbohydrates and fats taken in as food, only the protein contains all the substances required for the building up of tissue. Therefore, an organism fed only on fats and carbohydrates constantly loses the protein part of its body cells and ultimately perishes from protein starvation. On the other hand, it has been proven experimentally that an organism may exist on protein food alone, but such an exclusively protein diet would not be economical for the organism, since it takes a great deal more work to split off the part necessary for the production of energy from the protein molecule than from the molecule of carbohydrates. Fat again seems to be best adapted for the creation of heat. We see then that all the three cardinal ingredients of food—protein, carbohydrates, and fats—are required to maintain life.

In monocellular organisms, or even within the alimentary canal of a multicellular, primitive organism, every cell is endowed with ameboid properties, capable of devouring food particles, the subsequent changes of which take place within the cell. In the higher animal organism, the food has to be prepared in a certain way before the body cells can assimilate and utilize it. These changes are effected by means of special juices secreted by the different digestive organs. The active principles of all these juices are the so-called ferments or enzymes. These latter substances are of great importance not only in digestion, but in a great many other vital functions of organisms, and it may, therefore, not be out of place in this connection to give them some attention.

Enzymes are chemical substances, the action of which is different from the usual chemical reactions. By their mere presence a very complex chemical substance may split up into two or more simple molecules, and at the end of the reaction the enzyme remains unchanged. The process which most frequently takes place under the influence of the enzymes is the splitting up of each molecule with an addition of water—a so-called hydrolytic cleavage. This peculiar action of the enzymes has a close analogy, as was pointed out by Oswald, in the chemical process of catalysis. By catalysis is meant a chemical reaction which is brought about by the mere presence of certain substances—catalysers. These catalysers increase only the velocity of a reaction, which would have taken place without the aid of the catalysers, only a great deal more slowly. Since the catalyser is unchanged in the chemical process which it brings about or hastens, a very small quantity of it is able to influence reactions involving large quantities of other substances.

Of the different chemical properties which the enzymes have in common with catalysers, we have to mention the so-called reversible action. By this is meant the property of the same enzyme to split up a complex molecule into two simpler ones and then again unite the two latter into the original complex molecule. As an example may be mentioned the enzyme, lipase, which acts on neutral fats, converting them into fatty acids and glycerine. It was shown that this enzyme may cause a hydrolysis of a substance analogous to fat ethyl-butyrate into ethyl-alcohol and butyric acid, and at the same time it will cause a synthesis of the two last-named substances into ethyl-butyrate and water, which may be expressed by the following formula:

$$C_3H_7COOC_2H_5 + H_2O \rightarrow C_3H_7COOH + C_2H_5OH$$
$$C_3H_7COOC_2H_5 + H_2O \leftarrow C_3H_7COOH + C_2H_5OH$$

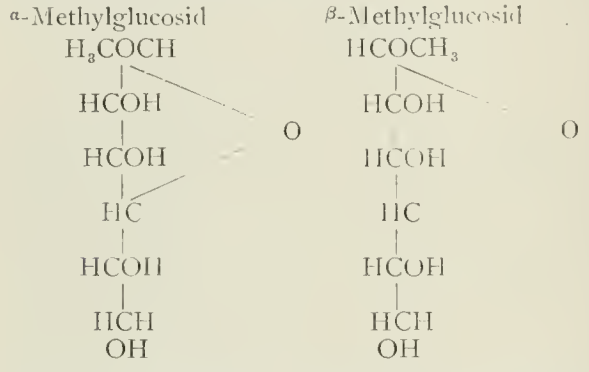
(Ethyl-butyrate) (water) (butyric acid) (ethyl-alcohol)

This property of the enzymes to reversible action is of the greatest importance in biology, as it clearly indicates that the most complex organic synthesis taking place within the cell may be caused by a purely chemical process without the help of some obscure vital property of the organism. Recent investigations have demonstrated that a similar kind of reversible action takes place during the cleavage of the protein molecule, giving rise to synthesis of

*Read by invitation before the Eastern Medical Society of New York on January 14, 1910.

more complex protein substances. It seems feasible then to suppose that the synthesis, which produces as a result protoplasm or living matter, also takes place by the help of certain enzymes. The same conclusion must be reached from the investigation of P. A. Levene, who has shown that in developing egg, *i. e.* in an egg, where new cells are being constantly formed, one can notice the breaking down of the albuminous matter and the appearance of products of the nature of nitrogenous acids, indicating the activity of some enzymes.

Another highly interesting property of the enzyme is its specificity. The majority of the inorganic catalysers, like the weak acids, are capable of assisting in a number of divergent chemical reactions. Enzymes, on the other hand, can exert their influence only on a certain well defined substance. There are given below the chemical composition of two substances, both sugars:



The only difference between the α- and β-methylglucosid lies in the different stereochemical positions of one molecule H_3. By a stereochemical configuration of a molecule is meant the fact that two substances may have exactly the same molecule, consisting of the same number of H, C, O atoms, but these atoms are situated in the molecule in the different relationship to each other. Such two substances having similar molecules, but with different stereochemical configuration are different chemical bodies and are influenced by different enzymes. As for instance α-methylglucosid is split up by invertin and β-methylglucosid by another enzyme—emulsin. This specific affinity of enzymes to a certain substrate indicates clearly that the enzyme is not acting as a catalyser only by its presence, but comes into closer connection with the component. Then when the reaction is completed the enzyme becomes free again. In other words, the action of an enzyme consists first in its anchoring to a specific group of the molecule of the substance and then in the catalytic cleavage of the molecule.

To this relationship between the enzyme and the substrate there is another very interesting analogy in that between toxin and antitoxin. Ehrlich elaborated a theory in explanation of the formation and action of toxins, which, as he showed subsequently, may have a very wide application in the explanation of action of drugs, intracellular assimilation of food, and in many other cellular functions. This so-called "Ehrlich's side chain hypothesis" explains the activities of the cell in a manner very similar to the specific action of enzymes. Each cell, according to this conception, consists of a central group of very complex molecular combinations, which performs the special function of this particular cell and which Ehrlich calls the function-nucleus (*Leistungskern*), and a great number of other groups, "side-chains" (*Seitenketten*), as he calls them. These latter have no importance for the special functions of the cell, but their main activity consists in the assimilation and burning up of food. Assimilation of food means a certain kind of chemical combination between foodstuffs and the protoplasm of the cell, consequently food, in order to be assimilated by the cell, must have a constituent part which is adaptable by the food receiving group—side chain—of the cell. Ehrlich calls the side-chain capable of receiving a certain foodstuff a receptor, and the molecule of the food adaptable to this receptor, haptophore group. And in the same manner as food is taken in, the cell may receive or anchor drugs, poisons, or toxins. In fact, Ehrlich considers the interaction between a cell and a poison or toxin identical with intracellular assimilation of food, and classes the toxins as spoiled, injurious foodstuffs. The difference, on the other hand, between the action of food and toxins on cell consists in the following: The food receptors, after having anchored the food, act on it as an enzyme, split it up and soon become free to receive another molecule of food. On the other hand, the receptors are not trained, or, rather, constructed to deal with toxins, consequently the latter either kill the cell through its toxophore group of molecules, or else remain permanently anchored to the receptor. The cell then loses this receptor for its own use, and, as is the case with every loss of a part of an organism, the cell begins to regenerate its receptors. Now, it is a general rule in pathology, that when a process of regeneration occurs, there takes place very frequently an over-compensation. In this case, then, more receptors are formed than the cell can hold; some of them are, so to say, excreted by the cell into the blood, where they circulate. These receptors circulating in the blood constitute the antitoxin. Toxin, in order to reach a cell, has to enter the blood, but there it immediately meets the free receptors, the antitoxin, combines with it and consequently become inoccuous to the cell and to the organism. We have a most remarkable proof of Ehrlich's assertion that the action of food, drugs, poisons, or toxins is identical in the fact that any of these substances introduced directly into the blood may give rise to the formation of antibodies, or may act as an antigen, *i. e.* a creator of antibodies. It has been mentioned before that a receptor, in order to perform its function, has to anchor a certain substance and then act on it as an enzyme. Certain receptors cannot perform this function unaided; they have to be prepared or activated by an additional substance, a condition which, as we shall see later, obtains also in a certain digestive enzyme —prosecretin. Such an activating substance is called amboceptor. As this name implies, this substance has two haptophore groups, one to anchor the cell, the other, the specific poison or food. The necessity of such an addition we find in the so-called cytolytic poisons, and, as a very interesting example of it, may be mentioned snake-venom. On introduction of this poison, the red blood corpuscles become dissolved. Now, this does not occur in every animal species; but in those animals where the reaction does not take place, it may be produced by an addition of lecithin, a substance which in itself is not capable of dissolving the erythrocytes. Lecithin is consequently in this case an amboceptor to the venom receptor of the red blood corpuscles; and if in the blood of another animal the reaction takes

place without the addition of lecithin, we must assume that the erythrocyte contains within itself lecithin in a form capable of acting as a complement. It is exceedingly instructive to learn how Ehrlich has demonstrated in his latest investigations that the action of drugs in curing disease is also identical to the assimilation of food. Trypanosomiasis means a class of diseases caused by penetration of animal parasites—trypanosomes—into the blood of animals and man. A trypanosome disease familiar to all is the so-called "sleeping sickness" occurring in Africa. It has been found lately that trypanosomiasis may be cured by certain arsenical preparations, atoxyl, arsazetin, etc. Not all cases, however, are cured. In some the disease relapses several times, and ultimately kills the animal or man. The same disease may be produced experimentally in rats or mice. Ehrlich has shown that in cases where these inoculated animals were cured with arsenicals, the parasites were killed by the drug. In those cases where relapses occur after treatment and the mice die, the trypanosomes not only remain alive, but acquire an immunity against the arsenicals. This phenomenon Ehrlich explains in the following way: When an arsenical is introduced into the blood of a patient or rat, it may either be anchored by the receptors of the body cells, and the parasite remains alive and ultimately kills the host, or the avidity of the receptors of the trypanosome to the drug is greater than the avidity of the cell receptor; then the arsenic is anchored by the trypanosome, kills it, and the patient recovers. Consequently, the result will be in every case a differential between the avidity of the two kinds of receptors to the arsenic. According to this conception, then, a trypanosome which becomes immune against arsenicals does not change qualitatively any of its constituent parts and still retains its receptor capable of anchoring arsenicals—chemoreceptor, as Ehrlich calls it—but its avidity to the drug becomes diminished. That this is so was brilliantly proven by Ehrlich in the following way: When a mouse is inoculated with immune trypanosomes and then treated with arsenic, the parasite remains alive and kills the mouse, but if the same immune parasite is placed in a test-tube and then arsenic added, the drug kills the parasite. Consequently the immune parasite retains its arsenical receptor, the avidity of which to arsenic is simply lessened, but in the test-tube, where the arsenic does not meet any other receptors, it ultimately anchors and kills the trypanosomes.

We have seen above that enzymes may split up complex organic molecules and also synthetically build up the complicated molecules from simpler ones. In the process of digestion of an animal organism, food is first split up into similar molecules, these are taken in by the different cells of the body, with the help of the food receptors, and there either split up further, in order to create the energy and heat necessary for the maintenance of the life and functions of the cells, or else synthetically built up into constituent parts of the body of the cell. Ehrlich's hypothesis offers us a certain conception of the intracellular assimilation of food. By digestion proper is meant the changes that foodstuff undergoes as it passes along the digestive tract before it is absorbed and taken up by the cells. This transformation is produced in a different way from the intracellular assimilation of food, inasmuch as the enzymes do not remain within the cells of the digestive organs but are secreted into the digestive canals, where they meet and act upon the food. I shall relate briefly the mode of their action.

The taking of food into the mouth is followed by the pouring out of saliva, which is produced by the different salivary glands. The use of this admixture of food with saliva is mainly mechanical. The saliva moistens the food and thus aids its mastication by the teeth, and also through the help of its mucin lubricates all the passages and facilitates the process of swallowing and the passage of the food bolus into the stomach. At the same time the food meets here the first digestive enzyme ptyalin, which transforms insoluble starch into dextrin and maltose. The secretion of saliva is caused by a reflex action of the gustatory nerves, and Pawlow has shown in his beautiful experiments on dogs with a salivary fistula how remarkably this reflex is adapted to the needs of digestion. He has demonstrated that, on administration of meat to a dog, the saliva which is secreted is derived mainly from the submaxillary gland, is thick and viscid, containing a relatively large amount of mucin. If, on the other hand, dry, powdered biscuit is introduced, the resulting secretion is thin and watery, and is obtained from both sets of glands. The introduction of stones into the animal's mouth evokes no secretion at all. The animal can get rid of the stones by movements of the tongue without any preliminary moistening. The introduction of sand into the animal's mouth is, however, followed by a copious secretion of a thin, watery saliva, which serves the purpose of washing the sand from the surface of the mouth and enabling the substance to be rejected by the animal. The same secretion of saliva may be evoked by merely showing the dog food, indicating that the cerebral cortex also takes part in these secretory reflexes. After the food has been reduced by movements of the jaw, cheeks, and tongue to a state of fine pulp, it is collected by movements of the tongue into a bolus. This bolus is then rapidly thrust by movements of the tongue muscles back into the upper part of the esophagus, its passage over the region of the pharynx is effected rapidly, so as to interfere as little as possible with the respiratory movements. Then from the upper part of the esophagus the bolus passes rapidly into the lower end and through the cardiac orifice into the stomach by means of a peristaltic contraction. These continual movements of the bolus play an essential part in the digestive act, and by their aid the food is intimately mixed with the digestive juices and gradually passes on from one segment of the digestive canal to another.

Upon entering the stomach, the food passes into the fundus and accumulates there to form one mass. The stomach remains passive for some time after the beginning of a meal, and it is not until twenty or thirty minutes later that the first movements of the stomach begin to appear, and, though the secretion of gastric juice begins while the food is yet in the mouth, it takes at least half an hour before that juice penetrates the whole mass of food, arrests the action of ptyalin, and converts the food into a soft mass—chyme. While these changes are going on in the fundus, in the pyloric end of the stomach there begin waves of contraction towards the pylorus. The effect of these waves is to force the food, which has been digested by the gastric juice and detached from the surface of the mass of food, toward the pylorus. The pylorus remaining closed,

the food cannot escape and therefore is turned back and again mixed with the gastric juice until at the arrival of one of these waves of contraction the pylorus opens and a part of the food is sent into the first part of the duodenum. The movements of the stomach can best be studied by Cannon's method; that is, by direct observation of the movements in a living animal, by means of *x*-rays. In order to make the shape of the stomach visible, the food is mixed with a quantity of bismuth subnitrate.

Gastric juice is secreted by the wall of the stomach, and the study of its character and mode of action presented great difficulties, since it was impossible to obtain it without the admixture of food and saliva, until here again the genius of Pawlow devised the necessary methods. His first experiment consisted in forming on the same animal a gastric and esophageal fistula. These animals can be fed either through the lower end of the cut esophagus, or directly through the stomach. They can also be fed through the mouth, but the food then falls out through the esophageal fistula without reaching the stomach. Such sham feeding produces a copious discharge through the gastric fistula of juice, free from admixture of food. By this method cannot be determined, however, the changes in the character of the juice produced by the digestion of food. To accomplish this Pawlow devised another operation. A small diverticulum, representing about one-tenth of the whole stomach, is made at the cardiac or pyloric end, in direct muscular and nervous continuity with the rest of the stomach, but shut off from the main part of the stomach by a partition consisting of mucous membrane only. Pawlow has shown that in a dog prepared in this way, the juices secreted by either of the two stomachs are identical, qualitatively and quantitatively.

What are then the conditions which determine the secretion of the gastric juice? The action of the sham meal indicates clearly that gastric secretion can be induced by a nervous reflex similar to the one acting on the salivary secretion, and Pawlow has shown that this reflex is conducted through the vagi. But, on the other hand, when meat is introduced directly into the stomach of a dog with a diverticulum, there also appears in the small stomach a secretion of gastric juice. Consequently, while the main amount of the gastric juice is secreted by the aid of a reflex nervous mechanism described above, a certain portion of the juice is secreted through the mere presence of the food in the stomach. Recent experiments of Edkins have shown conclusively that the secretion of this part of the juice is not caused by a nervous reflex, but by a complex mechanism, which, as we shall see later, was first described by Starling for intestinal digestion. Edkins showed that an intravenous injection of a decoction made by boiling pyloric mucous membrane in water produced a flow of gastric juice. He concluded, then, that the first products of digestion act on the pyloric mucous membrane, and produce in this membrane a substance which is absorbed into the blood streams, and carried to all the glands of the stomach, where it acts as a specific excitant of their secretory activity. Such a substance Starling calls a gastric secretin, or gastric hormone (from the Greek *ορμάω* arouse or excite). Such chemical messengers or hormones, *i.e.* chemical agents exciting certain specific activities, Starling considered of great importance in functions of the organism.

The gastric juice contains the first proteolytic enzyme to act on food, namely, pepsin. This enzyme forms an unstable compound with hydrochloric acid. In this acid combination pepsin acts on the proteins of the food, but its action is rather weak, and it converts the proteins only to its first products of hydrolysis, namely, albumoses and peptones, while, as we will see later, the other proteolytic enzymes convert the proteins into much simpler molecules. This is one of the reasons why the majority of physiologists held that the stomach plays an insignificant part in the digestion. A recent joint investigation of P. A. Levene, Manson, and the writer indicated clearly that while the gastric digestion may not assist in sending to the organism the substances needed for the production of heat and energy, it contributes greatly in the process of protein assimilation and repair of the protoplasm. The stomach also apparently contains another enzyme, lipase, which splits up fat in glycerin and fatty acids. Thus enzyme action on all constituents of food begins in the mouth and stomach.

On entering the duodenum, the first part of the small intestines, the fluid food—chyme—meets the three most important digestive juices, the pancreatic juice, the bile, and the intestinal juice. In order to study the pancreatic juice, Pawlow devised a permanent fistula, which consists in main in suturing the duct with a part of the duodenum to the abdomen. By the aid of this operation can be determined the normal relation of the secretion of pancreatic juice to the process of digestion. It is very interesting to note that, while the greatest quantity of gastric juice is poured out in the first hour after the meal, the maximum flow of pancreatic juice occurs in the third hour, at a time consequently when the largest amount of chyme is passing from the stomach into the duodenum. This remarkably well regulated mechanism of pancreatic secretion was shown by Starling and Baylies to occur in the following way: The cells of the mucous membrane of the intestines produce continually a substance, prosecretin, which has in itself no activity. When hydrochloric acid enters with the chyme into the duodenum, it changes the prosecretin into secretin, a hormone, as described above, which through the circulation enters the pancreas and incites a flow of its juice. The pancreatic juice, alkali in reaction, neutralizes the hydrochloric acid and arrests the formation of secretin until another part of the chyme with hydrochloric acid enters the duodenum. Here, then, is a perfect type of a chemical regulator of secretion of digestive juices, and, as Starling seems to have shown, this method of regulation takes place also in the secretion of pancreatic juice, bile, and intestinal juice to the complete exclusion of all nervous influences.

Pancreatic juice contains three enzymes—Amylopsin, which converts starch into dextrin and maltose, and then the latter into glucose; lipase, which splits up neutral fats into fatty acid and glycerin; and trypsinogen, which under the influence of an enzyme, enterokinase, contained in the intestinal juice, is transformed into the active enzyme trypsin. Pawlow holds that eterokinase acts on trypsinogen also as an enzyme and calls it, therefore, the enzyme of enzymes. Trypsin acts on the proteins of the food more powerfully than pepsin, and splits it up into simpler molecules than albumoses and peptones.

In order to study the characteristics of the intestinal secretion, a so-called Thiry-Vella fistula is formed, an operation which consists in the excision of a loop of the small intestine. This loop retains its connection with its mesentery, and both ends of it are left open and brought into the abdominal wall.

The intestinal juice, as was mentioned above, contains secretin, enterokinase, and besides this another proteolytic enzyme discovered by O. Cohnheim, erepsin, which cannot act on the original (native) protein of the food, but acts on the albumoses and peptones, splitting them up into simpler molecules, and in this way apparently completes the work of pepsin and trypsin. Furthermore, the intestinal juice contains three kinds of enzymes acting on carbohydrates: Maltase, which acts on maltose; invertin, which acts on cane sugar; and lactose, which acts on milk sugar.

Bile is mainly an excretion, representing the channel by which the products of distintegration of hemoglobin are excreted by the organism. As a digestive fluid, bile contains a weak amylolytic ferment, but most important is the part played by the bile in the digestion and absorption of fat. In an investigation of the influence of bile and pancreatic juice on the absorption of fat, the writer has shown that the combination of both juices is necessary for this function, and that neither with the pancreatic juice nor with the bile alone can the absorption be complete.

The digestion proper, *i. e.* splitting up of food molecules, ends in the upper segment of the small intestine. In the lower segments of the small intestine and in the colon there takes place absorption of fluids, and in the colon the function of excretion of remnants of foodstuff.

If we now consider what are the essential factors in normal digestion, we shall notice first that all the organs taking part in this function are finely adjusted for intercorrelation of their functions; for instance, pancreatic secretion does not start before chyme enters the duodenum; second, an organ like the mouth, which takes part, as it were, in the acquisition and selection of food, and which has to act quickly, is controlled by a nervous sensory reflex, while the pancreas, whose function consists merely in correct chemical action on a partly prepared food, is under the influence of a chemical regulator. Third, what is probably of the greatest importance in the economy of the organism, the factors of safety, as Meltzer states it, which we see in the luxurious construction of the digestive organs. For each cardinal ingredient of food, there are two or more enzymes throughout the different parts of the digestive organs, and normal digestion can take place, even if a good part of the digestive organs are inactive.

Let us turn now to the second part of our discussion. It must be clearly understood that by the pathology of digestion is not meant the enumeration of the anatomical changes of the different parts of the digestive tract, nor a description of the clinical pictures of the various diseases, but the study of the abnormal, diseased state of the functions of the digestive organs. These functions may be changed either quantitatively or qualitatively. In the former case the cells of the organism, and, consequently, the organism as a whole, will not receive a sufficient amount of food, and there will ensue a state of inanition or starvation. If the disturbance of the digestive functions is of a qualitative nature, this may lead to absorption from the gastrointestinal tract of the substances not completely digested, or products of abnormal cleavage. On entering into the circulation, these substances may exercise a toxic effect on the organism.

Let us investigate now how each of these conditions may affect the digestive functions of the different segments of the gastrointestinal tract. In all diseases of the mouth and pharynx, the intake of food may be diminished through pain or impairment of muscular action. Furthermore, the secretion of saliva may be either diminished, as in some infectious diseases, like typhoid or pneumonia, in which case the food will not be well prepared for the act of deglutition, or else the secretion of the saliva may be increased in quantity as it occurs in different kinds of stomatitis. Such a condition may impair the digestion through the neutralizing effect of great quantities of alkali saliva on the hydrochloric acid of the stomach. But what is more important, stomatitis is usually associated with an accumulation in the mouth and subsequent transportation into the stomach of numerous bacteria, which may give rise in the stomach to abnormal fermentations, with subsequent toxic effect on the organism.

The diseases of the esophagus all interfere with the deglutition of food, and consequently may cause inanition, but unless the disease itself be incurable, as is the case in carcinoma of the cardia, or in the diverticulum of the esophagus, the danger of starvation is comparatively slight.

Of the diseases of the stomach the only condition which may endanger the organism primarily through inanition is the complete obstruction of the pylorus, when the food cannot enter the duodenum, where the most important digestive changes take place. All the other gastric disturbances may be divided into two main groups. First, the diseases accompanied by increased secretion of gastric juice and hydrochloric acid. These conditions do not impair the digestion in a direct way, but bring on inanition through vomiting and severe pain, which may cause the patient to refuse taking nourishment. Of much greater importance are the conditions where the secretion of gastric juice and hydrochloric acid is completely absent, as in conditions of achylia gastrica, or carcinoma ventriculi. In these conditions the organism does not suffer, mainly through lack of gastric digestion, as the function of the intestines is ample for all purposes of nutrition. Through the lack of the stimulus which is usually given by hydrochloric acid, the pylorus does not open promptly to receive the chyme, and the food stagnates in the stomach. This allows the bacteria, always entering the stomach with the food, to form different products of decomposition, and consequently have a toxic effect on the organism. Under normal conditions it is not only the constant movement of the contents of the stomach that interferes with the activity of the bacteria, but the hydrochloric acid acts on them as a mild antiseptic.

Such a lack of evacuation of the stomach brings about the dilatation of the organ and, consequently, still greater retention of food and its products of decomposition. The same condition naturally takes place when there occurs primarily not a change in the quantity of gastric juice, but a dilatation of the stomach from paresis of its musculature. Pawlow has given an experimental proof of the fact that the disturbances of deglutition and motility of the stomach do not cause an actual inanition. The experiment consisted in cutting both vagi in a dog with

gastric fistula. In such an animal there occurs complete paralysis of deglutition and severe impairment of the motility of the stomach. Pawlow succeeded in keeping such a dog alive for months by feeding through the gastric fistula with the proper kind of food, and by washing the stomach after each feeding.

The diseases of the liver and gall-bladder have no direct influence upon the quantity of food prepared for assimilation. The bile, as we have seen before, exerts its influence only on the digestion and absorption of fat, but we know that not only is it sufficient for an organism to digest only a small fraction of the amount of fat taken in with the food, but even all the fat may be replaced by carbohydrates.

The pancreas is the most powerful digestive organ; still, if all the other digestive organs were normal and the pancreatic secretion should cease, a sufficient amount of food could be digested for the maintenance of the life of the organism.

The part played by the intestine in the digestion of food, independent of the stomach and pancreas, is comparatively small, and the influence of its diseases on the organism consist mainly in the loss of power to neutralize the bacterial and other poisons introduced with the food.

We see, then, from this brief review of the pathological conditions of the digestive organs, that the main danger to the organism lies in intoxication by foodstuffs only partially digested in the gastrointestinal tract, or by products of the metabolism of bacteria always present in every segment of the digestive organs. All these toxic substances on entering into the circulation exercise a deleterious effect upon every organ of the body, skin, circulatory system, even the mind. The most remarkable illustration of the dependence of every organ of the body on the functions of the digestive organs we see in pellagra. The disease is caused by faulty corn, as was conclusively shown by Lombroso. It begins with stomatitis, continues with gastric disturbances, then with skin lesion, and finally ends with depressive insanity.

THE PSYCHOLOGY OF THE CONSUMPTIVE.

By MAURICE FISHBERG, M.D.,

NEW YORK.

In no chronic organic disease other than of the nervous system, are we told as much about the importance of the psychic control of the patient as a prerequisite of successful treatment as in pulmonary tuberculosis. While administering digitalis to a patient with a failing heart, quinine in malaria, mercury or the iodides in syphilis, etc., we expect cooperation on the part of the patient only so far as is necessary to follow the directions given, coupled with such dietetic observances as may be indicated in the particular case. The psychic state of the patient, his confidence in his physician, as well as in those around him, are of but minor importance. Mercury will, in the vast majority of cases, dissipate the secondary manifestations of syphilis, the iodides the tertiary; salycilates will relieve the pains of rheumatism, and iron will enrich the blood with hemoglobin in simple anemia irrespective whether the patient has "complete and absolute confidence in his physician" or not. In cases of chronic pulmonary tuberculosis the case is different. How often do we meet patients who keep on sinking while under the care of one physician, but for one reason or another are impelled to change their medical adviser, and though the latter does not make any changes in the treatment at all, the patient begins to gain in health and well being. Every one who has many consumptives under treatment meets with such cases quite frequently. Indeed, I have seen many cases of tuberculosis which were going from bad to worse, but after a careful and minute physical examination by some pedantic physician who subjected them to all the procedures of physical diagnosis—detailed inspection, palpation, auscultation, and percussion; then he "gave them the benefit of the most modern diagnostic aids," the *x*-rays, opthalmic or cutaneous tuberculin test; examined the sputum and urine in their presence, etc., but as usual instituted no changes in the treatment beyond giving them same directions in different words than those given by the former physician. Yet this was the beginning of a most remarkable improvement in their condition. They began to gain in weight and strength, their appetite improved, and the cough was ameliorated. Similarly, although we are apt to dismiss the recent fads and fancies of the different kinds of "mind cures," including Eddyism, Emanuelism, and all other innumerable "isms" as occasionally beneficial only in functional or imaginary diseases, yet it is well known that many consumptives beyond doubt have been benefited by this sort of treatment, even of the "absent" variety.

These facts, and many others to be spoken of further on, indicate that in tuberculosis, an organic disease *par excellence*, the psychic state of the patient plays a great rôle in the symptomatology as well as in the treatment. To be sure physicians have recognized the psychic factor at all times. Hippocrates, Galen, Aretæus, and Celsus; later Boerhave, Auenbrugger, and more recently Laennec, Romberg, Trousseau, and others, have called attention to the influence of the mind on the body. But our recent materialistic conception of the life and functions of the human body, our great achievements in the fields of physiology and pathology, have diverted our attention from the psychic forces of the average patient. We carefully study the lesions in the lungs of the consumptive; we are able to determine accurately the extent of invasion of the tubercle bacilli and we form our final judgment on these objective findings, as well as on observations of the pulse, temperature, loss of weight, etc. Very few writers on tuberculosis have taken into consideration the mental or psychic state of the patient, though many mention the importance of perfect discipline and the influence exerted by the physician. That there is a psychological basis for these phenomena will be seen from the following facts.

The attention of physicians has been drawn to the relation of the nervous system to tuberculosis by the large number of consumptive insane especially in asylums. While a considerable proportion may be due to the overcrowding as well as the untidiness and carelessness of the demented, still even in asylums which are not crowded and among insane who suffer from the milder forms of mental derangement and take pretty good care of themselves and their surroundings, the number who succumb to tuberculosis is excessive. Clouston states that two-thirds of the deaths among idiots result from tuberculosis and that this disease is found three times

as frequently as a cause of death among insane as among the sane of the same ages. He adds that the graver, the more prolonged, and more incurable the form of insanity, the higher is the death rate from this cause. As far back as 1863 that author has made a special study of the relation of insanity to tuberculosis and among his conclusions it is of interest to note that there is a form of insanity so distinct in mental symptoms and clinically so characteristic of pulmonary tuberculosis that it may be called "phthisical insanity." He believes that the chief of the constitutional condition is probably a general debasement of the nutrition of the tissues and organs of the body, especially, perhaps, of the lungs. This may mean that certain nervous centers governing nutrition have been weakened in action. Whether tuberculosis is a cause of insanity or the reverse, whether insanity predisposes to tuberculosis has been discussed in medical literature quite extensively though there appears to be no unanimity on the problem. One thing is certain: The recent improvements in the sanitary and hygienic conditions of insane asylums have not materially reduced the mortality from tuberculosis among the inmates. F. Jessen brings conclusive evidence to this effect.

It is also a well-known clinical fact that the number of consumptives who display symptoms of neurasthenia, psychasthenia, and hysteria in their various manifestations is very great. As far back as 1689 this was already observed by Richard Morton. A large proportion of consumptives complain of vertigo, headache, pains along the spine, irritability of temper, insomnia not necessarily due to cough or nightsweats, and fleeting pains in the chest which at times cannot be attributed to circumscribed pleurisy; frequent attacks of tachycardia irrespective of the temperature and occasionally bradycardia are also observed. Then the languor and persistent weariness not relieved by sleep, but, on the contrary, many state that they feel much more weary and tired in the morning on getting out of bed, and that this tired feeling wears off in the afternoon or evening, all of which is quite suggestive of neurasthenia and psychasthenia. There is little wonder that many cases of tuberculosis are treated for neurasthenia until a careful examination of the chest reveals the true state of affairs. Papillon even goes so far as to say that he suspects every victim of neurasthenia to be a subject of latent tuberculosis. Considering that neurasthenia is at present attributed to toxic causes, it is evident that the toxemia of tuberculosis may reasonably be taken as the cause of these symptoms.

Of greater interest to us in this study is the psychic state, the *état d'âme* of the average consumptive who is by no means insane. I refer to the greatest majority of tuberculosis victims of either sex who with the onset of the disease, and often even before we can discern the physical conditions with the means at our command at present, show a remarkable change in their mental traits and character, a disturbance in their emotional life and a striking divergence from their previous habits, customs, affections, and tastes. These changes in the characteristic frame of mind and disposition of the consumptives has been observed throughout the course of the disease, ameliorating as a rule, with every improvement in his condition and aggravating with each exacerbation. What follows is based upon observations on several thousands of consumptives whom I met more or less intimately in my practice, and also on the literature on this subject, especially the studies of Heinzelmann, Engel, Rénon, Daremberg, Naumann, Mircoli, Mathieu, Letulle, Saxe, and others.

The first important psychic trait of a large proportion of consumptives that struck me as peculiar is their selfishness, especially in regard to social sanity. It is well known what sacrifices the poor make in their efforts to raise their children. We meet daily, in our rounds among our patients, with parents who do not hesitate to spend their last penny procuring some milk for their hungry infants without giving a thought to the fact that they ought to have some nourishment for themselves. We have yet to see a sober parent who would take milk, eggs, bread and butter, etc., for breakfast and allow his children to go to school with an empty stomach. The contrary is almost invariably true of the poor. This instinct of the preservation of the offspring, a trait of higher physical and mental organization is, as far as I have observed, attenuated among a large proportion of consumptives, and often entirely lacking among the consumptive poor. I have seen consumptives drinking a quart of milk and eating a couple of eggs in the morning while their anemic and emaciated children had to be satisfied with a roll; I have seen them eat a pound of beefsteak and other costly food while their children went hungry. I have met with consumptives who were members of fraternal and benevolent societies and entitled to sick benefit for a number of weeks and to a certain sum in case of death, sell their policy for a small sum "in order to save themselves by going for a few months to the mountains," as they stated, and thus leave their families in dire distress after they die. In no other chronic disease which has a profound influence on the psychic state of the patient, such as organic heart disease, cancer, etc., even neurasthenia, hysteria, and the sexual neuroses included, can we see such egotism, such selfishness, lack of generosity and charity and ready yielding to the temptation of gratifying the impulse of the moment at the expense of social rightness. They make strenuous efforts to turn everything in their own favor and do not hesitate to take away the last penny from their relatives and friends to go to the Catskills, Adirondacks, or Rockies even after several physicians have told them that they will not be benefited by the sojourn in the mountains. I recall a recent case of a fairly intelligent and self-respecting young man suffering from moderately advanced tuberculosis with laryngeal complications who was told by several physicians that he is not a suitable case for a high altitude. But he knew better. Having exhausted the pockets of all his relatives and friends he applied to a charity society for a ticket to Arizona which, on the advice of the physician, was promptly refused for obvious reasons. He, however, succeeded in persuading a charitably inclined gentleman that his life might be saved by the trip. About one month after he left New York I was reliably informed that this young man was found in a maniacal state walking in the streets of Phœnix and admitted to an insane asylum, but soon discharged and with the assistance of some other well-meaning people shipped to southern California. But about two months later he again appeared before me in New York begging for a railroad ticket to Arizona. He told me that a charity society in Los Angeles had sent him back to New York, but here he can see no relief, while in Arizona he is convinced that he will be cured. This unfortunate succeeded in inducing the gentleman who originally sent him to Arizona to pay for his trans-

portation again to the same region. About three months later I again met him and he again begged for a ticket to Arizona. He told me that he drifted to Colorado where, found starving, he was sent back to New York by a charitable society. He told me that he was not ashamed to ask his original benefactor for another railroad ticket, but unfortunately he was out of town. The only thing he wanted from me was a letter to a certain clergyman, which I refused. He however succeeded in convincing that clergyman that his life could be saved by a ticket to Arizona, where I believe he is now; if he is alive, I shall not be surprised at his reappearance begging for another ticket to Arizona.

I have known another case of tuberculosis whose mental make-up is worthy of note: A widow whose husband died of tuberculosis, and left her with five children penniless. Several months later she also began to show signs of the disease, but of a mild chronic type. She was assisted by a charity society with rent and living expenses. When she was given an order for shoes she inspected all that were offered to her, but did not like any. She offered the difference in price from her own pocket for a pair of shoes with French heels. Had this been accepted, her six children would have had to go without food for a week, because the money was part of what she received for this purpose from the society. In this case feminine vanity was coupled with lack of consideration for her underfed children. Vanity will often make a woman quite extravagant, but will never rob her of the moral consciousness inherent in the mother.

Many authors have attempted to define the peculiar psychology of the consumptive which in some cases reaches an extreme degree. Jessen believes that it consists essentially in a defective equilibrium in the mental and emotional state of the patient. Stimuli which do not disturb the normal and healthy brain are sufficient to derange the central nervous system which is affected by the toxemia of tuberculosis. Their judgment is weak and defective, as is evident from their well-known optimism, with which they deceive themselves about their real condition. Engel believes that the original, innate temperament of the individual becomes strikingly pronounced in the chronic consumptive: The pessimist suffers from marked despondency; the optimist becomes unreasonably hopeful of the outcome, etc. He explains these phenomena by the discordance between the subjective feelings of the patient who is not as disabled as the objective findings of the physician show. The mental make-up of the patient depends greatly on his physical condition, which in tuberculosis is subject to frequent variations; aggravations and improvements coming and going quite unexpectedly. The mental traits *per se* do not change, but such traits as were characteristic during youth, but as a result of education, training, and the vicissitudes of life, have been suppressed, reappear boldly unhindered by conventionalities. Saxe says the same in different words. He thinks the keynote of the mental changes of the consumptive is the gradual loss of will power, of self-control which, so to say, unmasks the man or woman. To this he adds that the ascendence of selfishness plays the most important part in the moulding of the mental traits of the tuberculous. In some patients these two factors are so pronounced that they completely reveal the concealed elements of their character.

I recall many cases in my own experience which illustrate these views. One, a man with criminal tendencies and who had served two terms in prison, was usually very kind and considerate to his mother and sisters. But since he became tuberculosis his character, as shown by his relations with his blood relatives, has completely changed; he, in fact, lost all power of self-control. He can no more treat his mother with the consideration due her, but on the contrary became her deadliest enemy. I read a letter which he addressed to his brother-in-law in which he accuses his mother of the most heinous crimes, and asks his brother-in-law how he can live with a wife of such an advanced age. In the later stage of the disease he became a confirmed slave to the needle, and living with his sister, he wantonly expectorates indiscriminately so that, "in case consumption is really contagious as the doctors say," all his relatives shall be infected. When threatened with forcible removal to a hospital with the aid of the Health Department, he flashes a revolver and states that he has nothing to lose by killing the whole family. Inwardly, however, he is not despairing of his condition, because he keeps on reading about the disease, consulting physicians, and hopes to recover, when he hopes to get even with his enemies. I know another chronic consumptive of excellent appearance and with a most remarkable power of speech, capable of earning his own living if he only consented to accept some easy employment considering that the lesion in his lung is in a quiescent state and his general condition is relatively good. He believes, however, that the world owes him a living, and writes letters to charitably inclined individuals and societies appealing "for his poor old mother," never for himself. He refuses to enter an institution because "his mother needs his care and affection during her old age." But as a matter of fact, he uses her as a tool to excite pity, and while he eats daily two quarts of milk, several eggs, and a pound of meat, he allows his old mother to exist on a starvation diet. These traits of his character manifested themselves only since he began to suffer with the disease.

The selfishness and ingratitude of some consumptives are best displayed in cases in which a married man or woman is affected. The healthy spouse can never prove that he or she does everything possible to save the patient. Unfounded suspicions that her husband wants to get rid of her, or that his wife is already contemplating marriage with some man, are quite common, much more common than among sufferers of other chronic diseases, such as cancer, heart disease, etc. I have made it a point to emphasize to consumptives the dangers of cohabitation, especially among the poor. Here, in addition to the risk of infection through intimate contact, I know that a pregnant or nursing widow has a harder burden, and that tuberculosis in a pregnant woman is very dangerous. But from experience with thousands of wives of consumptives, I find that very few succeed in keeping out of their sick husband's embraces. Many beg that their husbands be taken away to some institution as the only means of keeping them away from them. I have known many cases of consumptives who impregnated their wives a few weeks and even within a few days before they died, in spite of all warnings on the part of the physician and all the resistance on the part of the helpless wife. I know

of cases in sanatoria who were permitted to go to the city for twenty-four hours to visit their families, and who cohabited with their wives, or even impregnated them, during that day, or the case of a woman who became pregnant during such a visit and returned to the sanatorium in that condition. I do not believe that this is always due to heightened sexual desire which some authors attribute to consumptives. I am under the impression that men are more liable to this kind of crime, for such it is, while women are only rarely guilty of it. The consumptive husband wants to make sure that his wife, who in his estimation has not done enough for him, should have a heavier burden to carry after his death.

Dealing with large numbers of consumptives in their own home, and not in institutions where they are restrained, I was struck with their selfishness, egotism, and lack of consideration for those dependent on them, which at times exceeds all bounds. The strange visitor can not see beneath the surface, and the patients usually appeal to charity visitors or dispensary nurses for their wives, children, or parents, as was already mentioned. All this is done with the usual cunning of the beggar, the mendicant, whose traits many poor consumptives who were formerly self-respecting soon acquire. It is evident that among the well-to-do and the rich the egotism can not assume the same forms as among the poor, but is by no means lacking. I know a cultured, well-to-do consumptive whose snobbishness and tactlessness brings him often in trouble. But whenever he is compelled to apologize for some indiscretion he does not fail to mention that he has "only one lung." And he is right, I believe; his excuse is based on a sound foundation. Another manifestation of the selfishness of the consumptive is seen in those cases whose egotism and loss of power of self-restraint exceeds all bounds, and as a result they can not accommodate themselves to institutional discipline. They often leave the sanatorium against the advice of the attending physician; their favorite excuse is that their families are starving and they feel well enough to go back to work. But when they return to the city they usually do not make any serious effort to secure employment even in case they are quite capable to make themselves useful.

The optimism of the consumptive, which has so much been exploited by writers of fiction, is evident from the onset of the disease. As soon as the patient is told that he has a "touch" of the disease, his despair does not last very long, especially now, since so much has been written for the laity about the curability of tuberculosis when taken hold of in time, and that advanced cases are not always hopeless. It is only a profuse hemorrhage that will terrify the average patient. The incipient victim of tuberculosis usually makes an excellent appearance. He is lively, confident, and full of hopes of a speedy recovery. Probably as a result of the general toxemia, he is overwhelmed with the disease and constantly speaks of his condition, gets everybody interested in his health and well-being. He keeps on visiting physicians, and while some tell him that he suffers from incipient tuberculosis, others tell him that he has only a "cold," a "catarrh," etc., and his illusory hopes are heightened. He is convinced that his family physician has only scared him in order to make him lead a regular life. In New York many of this sort of patients now go from one of the tuberculosis clinics to another, giving everywhere another name because, as one told me, they placed him on the black list and they will everywhere tell him that he is a consumptive if they know who he is. A large number do not want to be known as consumptives, at times because they can not find lodging, but more often to avoid the stigma which has of late been placed on them by the antituberculosis crusade. With the progress of the disease their optimism assumes often another form. His vivid illusions of a quick cure are beginning to vanish; he fears that the disease is likely to kill him, and death appears to him horrible. As was already shown, his innate characteristic traits reveal themselves now in an accentuated form; especially those that were bad. He becomes a sore-head, a grouch, a grumbler. He is easily provoked, irritable, and quick changes of temper from hilarity to depression manifest themselves. Some become actual recluses, avoiding those who offer consolation and sympathy, hate many who were formerly dear to them, and become altogether despondent. It is noteworthy, however, that such cases are comparatively uncommon. The fact that very few consumptives commit suicide shows how rare actual despondency is to be met with. The vast majority of consumptives, even those who appear discouraged, are always hopeful in their heart of hearts. They are constantly on the alert for some new remedy, and are the victims of quacks more than other chronic sufferers. One patient of mine who always begged for poison to make an end to his sufferings reported to my office immediately on my return from the last International Congress on Tuberculosis with the special object to find out whether some new remedy has been reported, and offered himself as a willing subject for experiment. When told that no new remedy has been reported, he again despaired and said that after all science is a sham, a fraud, if it can not overcome such a small organism as the tubercle bacillus.

Their hopefulness, in spite of apparent despondency, is shown by their explanations of the changes in their condition. If their cough is aggravated, it is because they have caught cold the other day when leaving the house while perspiring, or due to change in the weather; if they have fever it is because they have eaten too much or have consumed a bad egg; if the pain in their chest is aggravated, usually due to pleurisy, they ascribe it to a draught while opening the window at night; if their appetite fails it is due to lack of exercise, of fresh air, etc.; their emaciation is of no importance, it is only due to the poor appetite, and if the physician would only give them a good tonic, they would soon gain in weight; their weakness and debility is due to nervous exhaustion, the result of the irritation on the parts of their relatives and friends, who never treat them right. They never want to realize their true condition; even those who are apparently despairing, telling everybody that they expect relief in death which is quick in coming, become very much alive when told of some new remedy which the newspapers announced; or of some quack who guarantees a cure..

The euthanasia of consumptives, which writers of fiction have exploited so much and even medical writers have often described, is not observed in all cases. Those who are overwhelmed with the toxemia of the disease, who are extremely emaci-

ated so that the dose of the toxin is large considering the smallness of the wasted tissues, are calm, peaceful, and often feel better apparently for a few days before death. The explanation is simple: The reflexes in these cases are practically abolished, the cough which troubled them formerly ceases now, all the aches and pains which made their life miserable have vanished, and they at times delude themselves that these are signs of improvement. In many of these cases the mind remains clear, and they dream of happier days, make plans for the future, and often wonder why their friends appear more alarmed than before. I have known one who wanted to marry a few hours before he expired. But not all consumptives have such a peaceful termination. Some realize their condition, and their end is frightful, because fear and terror is the dominant note. Their face expresses an atrocious terror, characteristic of consumptives who have despaired. They keep on inquiring when the end will come, how soon they will be relieved from their terrible physical and mental sufferings. These cases are rare. Most of the consumptives do not realize their true condition, and never know the approach of death. A few minutes before death he may ask his betrothed to prepare for the wedding, as I have seen in one case; he may plan a long voyage to regain his vanished strength. They often begin to indulge in some hobby which they hope to follow as soon as they can leave their bed; "as soon as that annoying cough stops," or "if those miserable night-sweats would not exhaust me so much I could do almost anything," etc. They thus deceive themselves until they sweetly and peacefully expire full of hope and aspirations.

Several authors, notably Bernheim, Baccelli, Saxe, Jessen and Mircoli, have spoken of the responsibility of the consumptive from the medicolegal standpoint. It is evident that the psychic state of the average tuberculous patient shows marked divergences from what we are wont to consider normal. The oscillating emotional manifestations, the alternating moods changing quickly from supreme exaltation to extreme depression, and his unwillingness or inability to realize his true condition even during the most ominous periods of his disease, show that his mind is not in equilibrium with his withering body. Some have drawn an excellent analogy between the consumptive who is in a state of intoxication by the toxines of the tubercle bacillus and the alcoholic. Indeed, the external appearance of the consumptive walking around with a subfebrile temperature are somewhat similar to those presented by one who is under the influence of alcoholic intoxication. The bright eyes, the dilated pupils, which contract at times, the rosy cheeks, remind one of the alcoholic, as Mircoli has pointed out. Mentally, also, there are great similarities: the flickering intelligence, which brightens up suddenly for a few hours to be soon followed by a depression of mentality; the impulsive actions, the perverse stubbornness, the egotisms which occasionally leads to criminal actions, combined with the quick transitions from optimism to pessimism, are seen among both alcoholics and chronic consumptives. That these are the effects of toxemia is evident when we consider the typical reaction of an injection of tuberculin and certain experiments with the toxins of the tubercle bacillus or some of the excretions of tuberculous patients, notably perspiration, which produce similar states of intoxication.

Bearing all this in mind, several authors have pleaded that the consumptive's responsibility should be limited by the law considering that their queer and unaccountable actions are performed under the influence of the tuberculosis toxine, for which they cannot be held responsible, and that they should not be harshly dealt with in courts of law. Mircoli is plain and ouspoken in his plea for the limited responsibility of the consumptive. Saxe says that the psychasthenia, the loss of self-control, and the rise of brute selfishness in some cases conspire to distort the clearness of the ethical perception, and cites several cases substantiating the irresponsibility of the consumptive criminal. I have met with several cases which confirm this view. In my experience this is especially true of those who realize the hopelessness of their condition, and, instead of resignedly waiting for the inevitable, or at most pleading for the relief of pain and discomfort during their last days, as is to be seen among patients who suffer from cancer, nephritis, heart disease, etc., they begin to manifest an intense dislike and even hatred toward those who appear bright and healthy. Such patients are apt wilfully and criminally to disregard all the injunctions against indiscriminate expectoration; even the fear of reinfection which keeps back many others from spitting, does not deter those who have despaired. They often watch whether any of their relatives or friends show any suspicious signs of tuberculosis, and I have seen some who regretted why nobody in their family has not been affected. One of my patients has regretted that his fiancée, who had spent all her savings and her health while attending to him during his protracted illness, remained in this bright world after his departure. Their jealousy knows no bounds. In sanatoria the patients who improve quickly are not only envied, but often persecuted by some who show no marked improvement in their condition. Especially is this true of the female patients, who actually begrudge every pound of weight put on by those who do well under the institutional régime.

Alienists agree that the responsibilty is to be limited in those who are so far deluded as to become incapable of estimating facts in their true relations; in other words, who lack a sense of proportion.

A consumptive who becomes obsessed by the idea that his relatives and friends are not doing their best for him; who pesters all his friends and unreasonably demands material assistance which they are not in a position to supply; who sits down at the table in the morning and swallows several eggs, a quart of milk and bread and butter, while his anemic and underfed children have to go hungry; who expectorates indiscriminately at times, with the avowed purpose of infecting others; who cohabits with his wife, and thus deliberately exposes her to the dangers of infection and pregnancy, etc., can by no means show any mitigating or minimizing circumstances in the usual course of events. But when, on inquiry, we find that before he became tuberculous he was as good and as considerate a man as can be expected; that he loved his fellow man and never perpetrated any antisocial act, we must acknowledge that the present change in his temperament, habits, likes and dislikes are not of his own choice or volition, but is the result of the intoxicating influence of the tuberculosis toxine. It is this toxemia that robs him of the sense of proportion, and in his instinctive desire to live he cuts loose from all ethical and conventional precepts. Of

course the advantages he may, in this manner, gain for himself are quite insignificant in comparison with the injuries he is apt to inflict on others. But such a disproportionate view of life can not be seen in a normal man or woman, and these actions are *prima facie* evidence that a consumptive who acts in this manner is incapable of estimating life in its true ethical relations. In our efforts to prevent the spread of the disease, and, incidentally, to prevent some of the anti-social acts of some consumptives, we are justified and often even called upon to restrain some patients whose actions endanger the life or happiness of their fellow man. We must forcibly remove all those who wantonly disregard all the injunctions against spitting, or are in any other manner making a nuisance of themselves, just as we remove other mentally perverse individuals in order to prevent them from harming others as well as themselves.

Major forms of crime are at times committed by victims of the advanced stages of consumption, as has already been stated. Ciofi, Chartier, Skulteki, Saxe, Mizcoli, Bernheim and others cite illustrative cases. Juries, as a rule, exercise great clemency in cases in which the defendant presents the stigmata of advanced tuberculosis; whether they know that he is a victim of psychic and somatic degeneration, or that he has acted under the influence of tuberculous toxemia, is immaterial. The fact is that it is quite difficult to obtain a conviction in such cases. But for medical men there is a wider field for prophylaxis. Advanced consumptives, who show criminal and anti-social tendencies, should be segregated in hospitals in the same manner as other persons with anti-social tendencies are segregated. This is at present not done to any reasonable extent. Most of the institutions for the care of consumptives admit only incipient cases, or aim in this direction, while the advanced cases, the ones that are most dangerous from all standpoints, are left to shift for themselves. Considering the perverse psychic state of some of these patients, and their anti-social proclivities, it becomes more and more evident that they ought to be segregated.

The peculiar mental traits of the consumptive have a great influence on the course, prognosis and especially on the treatment of his disease. In tuberculosis, just as much as in other diseases, it is the patient and not the disease that is to be taken care of. In the absence of a specific cure at the present state of therapeutics, we must rely on palliatives when we have a case of tuberculosis under treatment, and it appears from the literature on the subject that psychotherapy is of immense importance in our dealing with this class of cases. This has been recognized by all those who have devoted their lives to phthisiotherapy. Dettweiler long ago spoke of the importance of psychic treatment, and insisted that the complete and absolute confidence of the patient is the foundation of phthisiotherapy. Brehmer was of the same opinion, and he pointed out that the patient can learn to control excessive cough. We can see how true this is while visiting sanatoria, where the majority of patients hardly ever cough. Cornet is emphatic in his statement that no success can be expected by merely giving detailed directions concerning diet, rest, and drugs unless a bond of sympathy is established between the physician and his patient. Most others, like Rénon, Miner, Sokolowski, etc., who wrote on the treatment of tuberculosis express themselves to the same effect. It is a noteworthy fact that sanatorium treatment depends mostly on psychic treatment for success in the vast majority of cases, and it is questionable whether institutions which admit patients of different nationalities, with different habits, customs, and tastes, can register as many ultimate cures as those that admit a uniform class of patients. It is also well known that the success of the average sanatorium depends greatly on the personality of the superintendent and the physician in charge. I meet with numerous patients discharged from sanatoria, and have been struck with the differences in the results they attained. I know of two sanatoria which admit the same class of patients, keep them about the same length of time, and treat them in practically the same manner. But the differences in the results are striking: From one sanatorium practically all the patients come out after remaining at least six months, usually longer, in the institution, while from the other a large proportion leave within two and even one month after admission. The reason is that in the last-mentioned institution numerous patients are expelled for disobedience of rules and regulations, while in the former this occurs very rarely. Moreover, in the latter institution, the patients are living in constant fear lest the superintendent will order them to submit to what appears to them most dangerous injections of tuberculin. They in some manner have a tradition in that sanatorium that tuberculin aggravates the disease, and, when their information is confirmed by actual fact; when one submits to tuberculin treatment and gets fever, malaise, pains in the muscles and bones, etc., they pass it around among their fellow sufferers. I know of many patients who refused to submit to this mode of diagnosis and treatment, exposing themselves to expulsion, the invariable punishment for this disobedience, and the concomitant starvation in a New York tenement house, because they are practically all poor artisans. The bulk of these patients are of a low economic and social class, and their intelligence is correspondingly low. But they tell me that their personal observation has convinced them that every patient who has been treated with 'injections" suffered severely. The result is that when one does submit, his mental fear, terror, and anxiety only aggravate the symptoms of the reaction, and it serves as an object lesson to his fellow sufferers.

The psychic effects of the tuberculin treatment has been recognized by many experienced phthisiotherapeutists, notably Rénon and Mathieu. The failure of this mode of treatment in the patients just mentioned is not unique. In others the effect is quite the opposite. Experiments made by Albert Mathieu show distinctly the influence of the psychic state of the patient on the success or failure of tuberculin. He announced to his patients that a great discovery had been made in the shape of a new serum which positively cure tuberculosis, and he gave it the important name "Antiphymose." He selected his patients carefully, examined them minutely, and noted daily the results attained by this wonderful remedy, which actually consisted in the injection of a few centimeters of physiological salt solution. The patients were greatly impressed with the new remedy, and the favorable results exceeded all expectations. After a few days' treatment he noted an improvement in the appetite, a diminution in the temperature, cough, expectoration, and night-sweats, and even an improvement in the physical signs. The patients began to gain in weight, ranging from 1500

grams to 2 and 3 kilograms. As soon as the injections were discontinued, all the old symptoms reappeared.

Such is the influence of the psychic state of the patients, as well as the personality of the physician on the symptomatology, course, and treatment of tuberculosis. In sanatoria in which the resident physician has not succeeded in gaining the absolute confidence and sympathy of the patients, both fare very badly. Tuberculin injections for either diagnosis or treatment is apt to have disastrous results. On the other hand, when patients who know about the modern methods in medicine from reading popular articles are told by their physician in detail about the wonders expected from a new serum, "Antiphymose," the suggestion is apt to work wonders. That this is not an isolated incident is known in medical literature. Engel observed that the temperature of a patient sank after an injection of Hetol, but he also obtained the same result by an injection of distilled water. Many tuberculous patients fall asleep after an injection of water; others have their cough and their pains relieved in a similar manner.

It is this psychic factor that quacks gamble on when they "undertake to cure consumption when all other physicians have failed." I have seen many patients treated in sanatoria whence they were discharged as unimproved or even worse, submit to treatment by some advertising quack, and they improved wonderfully. I know many immigrants who contracted tuberculosis while laboring in the New York sweatshops and could obtain no relief in sanatorium or home treatment. As is often the case with immigrants, they began to long for their native home, where they felt confident they could be cured. Some of these have gone so far downward in their health that the steamship surgeon hesitated to admit them on board, fearing they could not stand the hardships of a long sea voyage. Yet I have often heard from their relatives that they began to improve as soon as they reached home and of many that have been cured in this manner. Some cases which I considered hopeless before they left for Europe, returned to New York after a sojourn of several months, a year or two, in excellent condition of health. That it was not the climate, nor the superior diet which contributed to the cure I am convinced from my knowledge of the sanitary and hygienic conditions, as well as the poverty in eastern Europe, whence the class of patients spoken of hail from.

It is also as a result of this psychic factor that the therapeutic measures recommended for the therapeutic treatment of tuberculosis, as long as they are harmless, always give the same proportion of satisfactory results. Rénon considers this an axiom, and says that he should like to write it down with large letters in all the new works of pthisiotherapy. It is an axiom which may be briefly and comprehensively stated in these words: "Hasten and take the new mode of treatment as long as it cures; delay may be dangerous; you may be too late." Indeed, comparing the results obtained by the various methods of treatment of tuberculosis, we find that they are always about the same. There is always a certain percentage "cured," "disease arrested," "improved," "unimproved," and, last, and in this case practically always least, "dead." A study of the literature of tuberculosis confirms this emphatically. All sanatoria, whether located on high or low altitudes, at the seashore or inland, in cold, warm, or moderate climates, irrespective of the special method of treatment, outdoors, indoors, or in tents; no matter what fad the attending physician believes to be of greatest importance, be it dietetic, medicinal, or specific, they all give the same results, if we may judge them by the percentages reported as cured, arrested, improved, etc., in their annual reports. Similarly, the several dozen kinds of tuberculin, each of which, in the hands of its discoverer, gives excellent results. Nor are drugs an exception, judging from the papers which appeared in the medical press during the first few years of their appearance, when they were urged by excellent observers as potent remedies for the disease. This can be seen from reports on creosote and arsenic and their derivatives, ichthyol, cinnamic acid, iodin and, the latest, the succinimide of mercury. They all cured a certain percentage, arrested the disease in a larger percentage, and failed in very few cases. All had a fair proportion of cures to their credit, which Rénon calls the "normal coefficient of amelioration," no matter what method of treatment was used. He explains this curious phenomenon by the psychotherapeutic factor which is the resultant of the faith which the enthusiastic physician has in his remedy and is able to imbue his patients with the same faith. In other words, it is mainly suggestion and autosuggestion which is efficacious. Rénon states justly that before accepting a method of treatment of tuberculosis as effective, we must first determine whether this "normal coefficient of amelioration" is exceeded; it must successfully survive the test of time; and it must also be tested in the same patient by different physicians or by the same physician—for a long time. Then, and only then, can a remedy be accepted as valuable in the treatment of tuberculosis.

THERAPEUTIC DRAINAGE IN ONE HUNDRED AND EIGHTY-FIVE CASES OF UTERINE OBSTRUCTION.

PRESENTING A NEW FENESTRATED RUBBER UTERINE DRAIN.*

By A. ERNEST GALLANT, M.D.,
NEW YORK.

CONSULTING SURGEON, JAMAICA HOSPITAL, NEW YORK, AND THE EASTERN LONG ISLAND HOSPITAL, GREENPORT, N. Y.; SURGEON TO THE BAPTIST DEACONESS' HOME AND TRAINING SCHOOL; SURGEON-IN-CHIEF TO THE AMITY DISPENSARY AND JONES MEMORIAL CLINIC, NEW YORK.

Every normal woman is provided with a uterus and adnexa, instinct with a trinity of purpose, secretion, reception, and expulsion. The unalloyed enjoyment and fulfillment of these functional activities depend primarily on the free and unobstructed egress of the secretions and ingress of the human seedling wending its joyous way to the ovular rendezvous. Unfortunately for many women, obstructions bar the way, and the excretions are dammed back; bacterial growth, resorption of toxins, septicemia, and disturbance of the whole economy takes place, and life itself may be threatened or even sacrificed.

Obstruction to menstruation was the most frequent and principal symptom, in this series of 185 cases, and associated with the following conditions:

	Anteflexion Cervix.	Retroflexion Body.	Fixation.	Retroversion.	Totals.
Dysmenorrhea—Before.	13	1	5	7	26 times
During.	23	3	9	16	51 times
After..	2	0	6	7	15 times
Menorrhagia	12	0	6	7	25 times
Metrorrhagia	3	0	2	5	10 times
Totals	53	4	28	42	127 times

Intermenstrual Obstruction.—While we all agree as to the importance and desirability of facilitating women in their laudable desire to become mothers, and are ready to execute measures for the regulation of menstrual irregularities and excesses, but too few seem to realize the great detriment to girls and women of the tortures of dysmenorrhea and the dangers of intermenstrual obstruction.

Physically what can be more distressing to the young girl whose first menstruation is announced by severe abdominal cramps with loss of blood, especially when she is taught to look forward to its regular recurrence, as to a horrible nightmare, a part of the "curse" which each woman must bear, and from which she can obtain relief only by violation at the hands of the surgeon. Psychologically she is oftimes undone, her mind being unduly centered on her sexual apparatus, curiosity leads to palpation, tittilation, masturbation, and may end in ruination.

For the obstructed uterus there is no rest, during the whole twenty-four hours of the three weeks, more or less, of the intermenstrual period. After menstruation ceases the uterus remains congested, an excess of mucus is secreted, accumulates in the uterus and must be expelled by frequently repeated contractions, bringing about muscular hypertrophy, thickening of the walls, and a dilated cavity. The heavy organ dragging on its ligamentous attachments excites numerous aches and pains.

It is our firm conviction, based upon careful study of several thousand women, that intermenstrual uterine obstruction is far more productive of chronic pelvic disease than the more readily recognized discomfort, distress, or actual suffering during menstruation, and is the real reason for this effort to interest you in the special plan of treatment which has been carried out in this series of 185 cases.

Obstruction and Reproduction.—Obstruction causing sterility occurred in 57 cases, primarily in 19, and secondarily in 13 who had been pregnant and borne children, miscarried, or both; with 24 in whom fecundity had not been recorded.

From a mechanical standpoint sterility was associated with version 26 times; fixation, 28 times; anteflexion of the cervix, 29 times, and retroflexion of the body, 3 times. Of other conditions prohibiting conception, there were two cases of septate hymen, two of hyperesthesia of the hymen, necessitating removal, and one of excessive coitus. In two husbands no spermatozoa could be found.

While we know that the treatment of twenty-eight sterile women has given forty-six children and two miscarriages, the sequelæ in this class of cases may not always accord with what had been hoped for, as in the case of Mrs. McG., a patient of Dr. T. T. Gaunt, who in March, 1899, was curetted, a drain inserted, and the uterus supported with a pessary. Three months later (July) a large hematoma was removed by celiotomy and found to have been caused by rupture of a left-sided tubal pregnancy. January 15, 1900, the celiotomy was repeated for the removal of a large, multilocular ovarian cyst on the right side; all within ten months. The patient has been well ever since, but deplores the loss of procreative power.

Obstruction and Retention, with well-marked evidences of infection after premature expulsion of the fetus, occurred in 34 cases (5 abortions, 12 miscarriages, 1 premature labor, 5 puerperal sepsis, 11 retained secundines), which were all drained, effectually demonstrating the notable efficiency of the drain in overcoming retention, absorption, and toxemia, as shown by the rapid subsidence of all symptoms within thirty-six hours of its introduction, with or without curettage, and the early rise of temperature, pulse, and respiration if the drain was prematurely withdrawn.

Obstruction vs. Pain and Headache.—Pain, to the patient at least, is the one thing to be relieved, and demands of us that it be traced to its source. Referred pain and headache were complained of and associated with the subjoined conditions:

Pain—Associated with Referred to the—	Anteflexion.	Retroflexion.	Fixation.	Retroversion.	Total.
Abdomen	3	1	0	1	5
Iliac region	10	0	6	8	24
Sacrum	12	2	11	19	44
Hips	2	1	0	4	7
Thighs	4	2	3	0	9
Knees	3	1	1	0	5
Legs	0	0	1	0	1
Totals	34	7	22	32	95

*Read before the American Therapeutic Society at its tenth annual meeting in New Haven, Conn., May 8, 1909.

Pain—Associated with Headaches—	Ante-flexion.	Retro-flexion.	Fix-ation.	Retro-version.	Total.
Vertex	3	0	2	1	
Frontal	1	0	0	2	3
Supraorbital	0	0	1	0	1
Temporal	1	0	0	1	2
Occipital	1	0	1	2	4
Totals	6	0	4	6	16

Sacral pain, the most frequent, the most prominent symptom (44 of 95), and the most constant seat of the suffering, was due to inflammatory changes in the uterosacral ligaments, adhesions in the pelvis following localized peritonitis, and the increased size and weight of the heavy, congested, hypertrophied uterus dragging thereon. On the other hand, it was always necessary to exclude the urethra and bladder, the anus, and rectum as the possible seats of the disorder.

Iliac pain in twenty-four instances was associated with similar conditions and led to drainage of the uterus, with appropriate surgery on the tubes and ovaries. The relief of persistent headache, as a reflex indication of flexion, version, or fixation, presents the most gratifying results following drainage and restoration of the uterus to its normal position.

Version and Obstruction.—From a mechanical standpoint the uterus may be likened to a bottle, lying in a nearly horizontal plane, upon the pelvic diaphragm. Under normal conditions, varying with the quantity of urine in the bladder, the uterus rotates backwards within a radius of 90°, its anterior surface being always in contact and resting against the bladder wall. Whenever, congenitally, through trauma or as the result of the dorsal posture during the puerperium, etc., the uterus turns backward and fails to rotate forward, it more nearly resembles a bottle with its mouth uppermost. Under these conditions, during menstruation it must first fill, then overflow, and the clots be expelled by uterine contractions—dysmenorrhea. This state of affairs was present in forty-two cases, and not infrequently in connection with anteflexion of the cervix, of which there were fifty-three instances. After the uterus had been rotated forward, untwisting the broad ligaments and restoring normal drainage, painless menstruation was established, the congestion diminished, the hypertrophied organ involuted, the bearing down ceased, the headache disappeared, and the patient was cured, symptomatically, so long as the uterus was supported by a suitable pessary inserted with the broad end resting behind the symphysis, and the drainage was free. (*Philadelphia Medical Journal*, May 2, 1903.)

Obstruction and Fixation were associated in twenty-eight cases as the result of pelvic peritonitis' pus tubes, or thickening of the uteroscral ligaments. Whenever possible, the uterosacral ligaments were gradually stretched after the plan of Thure Brandt, or forcibly elongated under anesthesia, adhesions broken up, and the freed uterus maintained by a pessary. When this plan was impractical, when pus tubes were present, or adhesions could not be separated by these means, as in twenty-two cases, celiotomy was done, and if necessary the uterus was suspended after the plan of G. J. Jarman, by suturing a loop of the redundant round ligaments directly to the abdominal wall, and of the sixteen cases but one failed, a syphilitic, in whom catgut instead of silk or cotton sutures were employed.

Obstruction furnished its quota of mortality, three deaths in 185 cases now under consideration:

Case I.—Postpartum sepsis and pneumonia. Mrs. S., patient of Dr. Davin. When seen, the eighth day after miscarriage, the soft, flabby, immobile uterus nearly filled the pelvis. Skin jaundiced. Both lungs congested posteriorly. Considerable débris scraped from the uterus, which under potassium permanganate irrigation contracted. Gauze packing introduced. No anesthesia. Hypostatic (?) pneumonia increased and death occurred on the eleventh day after miscarriage.

Case II.—Postpartum septicemia. Mrs. McG., outpatient of the Mothers' and Babies' Hospital. Curettage the eighth day after labor, without anesthesia, brought away placental shreds, from the five-and-a-half-inch, flabby uterus, which did not contract. She died in profound sepsis one week later, the fifteenth day postpartum. (*Medical Journal*, New York, August 11, 1906.)

Case III.—Pneumococcemia. E. S., a physician's daughter, virgin, had been troubled with an irritating vaginal discharge for some months, also dysmenorrhea and fissure in ano. Under ether, dilatation of the hymen disclosed a follicular vaginitis. Cervix dilated and gold drain introduced; ichthyol gauze pack in the vagina. On the fifth day, when dressed and ready to go home, she had a severe chill, temperature 103° F. Five days later blood drawn from the median basilic vein, and smears from the vagina and cervical canal, taken by Prof. Ellsworth Elliott Smith, showed pure cultures of pneumococci.

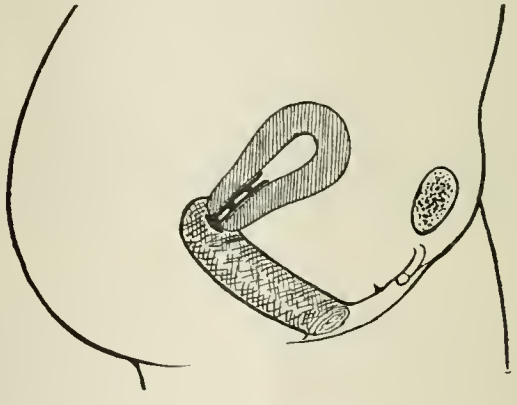

Fig. 1.—Fenestrated rubber uterine drain in the cervix; a roll gauze wick in the vagina.

Locally, there was only a small area of slough around the external os. Without developing any other demonstrable lesion elsewhere, she died on the nineteenth day after the initial chill.

Summary of treatment for the permanent relief of uterine obstruction:

(a) In case of obstruction, with or without flexion, evidenced by pain when passing a sound through the internal os, by a typical menstruation, by sterility, or by intractable headache, the cervix must be dilated to 38F., the cavity curetted and irrigated, and a bivalve or fenestrated drain sutured into the cervix, there to remain for from four to six months.

(b) When obstruction is associated with sepsis following abortion, miscarriage, or labor, in addition to the three-inch drain which has been inserted, a roll gauze wick (Fig. 1) must be introduced into the vagina and made long enough to protrude between the labia so as to come in contact with the vulvar pad, thus establishing continuous drainage from the interior of the uterus to the outside pad, a very important factor in the prevention of vaginal absorption and toxemia.

(c) When obstruction is combined with version

the fundus must be rotated forward and supported by an Albert Smith pessary, inserted broad end down and resting under the symphysis.

(d) Shortened, tender uterosacral ligaments and adhesions may be gradually stretched after the plan of T. Brandt, or forcibly loosened under anesthesia; these means failing, resort must be had to vaginal or abdominal celiotomy to free the uterus, and if need be resection of the adnexa, and suspension of the uterus by the round ligaments.

(e) In married nullipara, or those who have been sterile for years and are approaching the time of their probable menopause, carrying a heavy, displaced, adherent uterus, hysterectomy offers the one plan for permanent relief and cure.

(f) Trachelorraphy has been practised in a few instances of deep laceration into the fornices, and where the cervix was greatly hypertrophied and cystic, but amputation has been abandoned, as it shortens and removes a part absolutely essential to the support of the uterus in its normal position. Perineorrhaphy should be done whenever the perineum resembles the web between the thumb and forefinger, viz., two layers of skin without any muscular structure between.

Fig. 2.—The bivalve uterine drain.

The bivalve drain first described in the Medical Record, November 22, 1902, is made of the two halves of a split tube, united to a cuplike base, separated one-eighth of an inch on the sides, to permit the cervical mucus to flow into the drain, mingle with the uterine excretions, prevent clotting and plugging of the drain and providing an unobstructed outlet to blood, lochia, and mucus every minute of every hour of every day of every month while it is worn, and finally restoring the cervix to its normal shape and caliber. This incessant drainage promotes involution and atrophy of the hypertrophied uterus, stops dysmenorrhea, regulates menstruation, and if established early in septic cases, will bring about rapid subsidence of all the symptoms of infection. (*New York Medical Journal*, August 11, 1906.)

The fenestrated rubber uterine drain (Fig. 2., Tiemann & Co.) has these advantages: It is not corroded by the acid vaginal secretion, as is the silver or gold-plated drain, is more easily introduced, and stays in place better; but it cannot be boiled without losing its cervical curve, really a matter of minor importance.

FATAL FACTORS IN PNEUMONIA.*

By G. WERLEY, B.S., M.D.,

EL PASO, TEX.

Lobar pneumonia will always be the final cause of death in many cases. It is the last disease of old age in the majority of instances. As a complication of the acute infectious diseases it is often particularly fatal. So, too, when pneumonia attacks individuals crippled by chronic disease of the heart, liver, or kidneys; or by diabetes, great obesity, or chronic alcoholism, the victim often goes down like a rotten tree before the wind. Anthrax, plague, and streptococcus pneumonias are much more fatal than simple pneumococcus pneumonia. Pneumonia complicated by meningitis is always fatal. If we class as lobar pneumonia every case in which it is the final cause of death, it will be attended by a mortality of 5 per cent. or more that is inevitable.

But why is the mortality so variable when the disease is uncomplicated? Why do different practitioners in the same localities have such varying mortalities? Why do some hospitals have a death rate of from 30 to 40 per cent., while others have 10 to 20 per cent? True, the virulence of the disease varies, but it can hardly be that some are always so unfortunate as to receive only the unpromising cases.

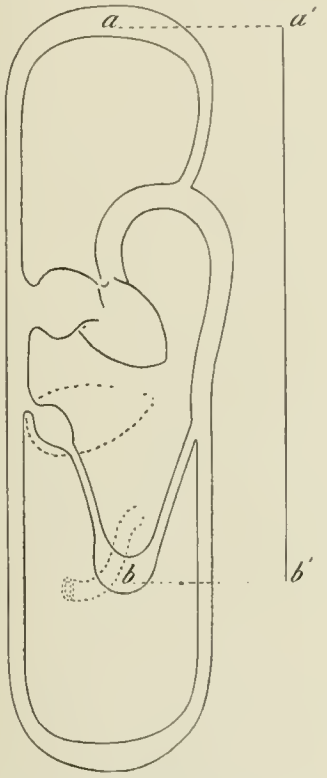

Diagram of circulatory system to illustrate the effect of position upon the vessels in the portal circulation. By constructing an apparatus with elastic bags at "a" and "b" and a Davidson's syringe in place of the heart it will be found that when the apparatus is placed horizontal on a table and the pump worked the two bags will dilate equally. But when the apparatus is placed vertically, and the pump worked with the same force as before, the bag at "a" contracts, while that at "b" dilates very much, owing to the fact that a column of fluid, extending from "b" to "a," now exerts hydrostatic pressure upon "b," in addition to that caused by the force of the pump.

I believe that much of the mortality is due to failure to realize the importance of a few underlying principles. The problem is a good deal like that presented by appendicitis. Recovery is a matter of placing the patient under the most favorable conditions to cure himself; with this difference that in pneumonia the natural means of defense generally effect a complete cure without the necessity of a subsequent operation to finish the work. In other words, the body by its phagocytes, its opsonins, and other means of defense will generally overcome the enemy if only given a good fighting chance and a little active assistance when plainly indicated. The great needs of the body in pneumonia are exactly the same as in health, viz., air, water, food, and proper rest, only the need for some of these is greater.

*Read before the El Paso County Medical Society, January, 1910.

F. Baumann[1] has well stated an important principle. He says, "it seems that the human system has in any given state of health only a certain well-limited amount of energy with which to perform its functions, consisting of building up, defending, repairing, reproduction, etc., and that by relieving the body of some of its work more energy will be at the disposal of defense and repair." It takes energy to overcome disease. The direct source of all the body's energy is oxidation. Withdraw the supply and death results in a few minutes. Insufficient oxygen means impairment of the whole mechanism of defense. I have calculated that a gas heater or oil stove of average size will consume as much oxygen as 10 or 15 people. Place one of these in the room, then add a few visitors and keep the doors and windows closed and your patient might about as well be in the Black Hole of Calcutta. The pneumonia patient needs and is entitled to the best air there is, and that is cool outside air, uncontaminated in any way. Northrup has proved that fresh air reduces the mortality in pneumonia. As long ago as the Civil War it was noted that pneumonia treated out of doors under apparently the most unfavorable conditions was less fatal than in the comfortable wards of hospitals. Giving half enough good air may be set down as the first great fatal factor in pneumonia.

It is altogether probable that the toxic substances generated by the pneumonia infection, like most other poisons and waste matter in the blood, are largely carried off by the urine. However that may be, these poisonous substances must be gotten rid of, and what are not destroyed or neutralized in the body should, if possible, be eliminated by the excretory organs. Other toxic conditions, like uremia, are treated very successfully in this way. The good results secured by Delancey Rochester[2] in pneumonia by his method of elimination through the skin, kidneys and bowels are practical proof that the mortality can be reduced by stimulating the excretory organs. Personally, my preference is to depend upon the kidneys almost entirely to carry off the poison. Simon Baruch[3] has proved that in the infectious diseases, the administration of four to six ounces of cold water every two hours increases the urinary secretions enormously. Practically we know that abundant urine is of good prognostic omen; scanty urine makes the outlook bad. Failure to give sufficient water may be set down as a not infrequent fatal factor in pneumonia.

Overfeeding and wrong feeding help to make pneumonia more fatal. Why? Because it takes energy to digest and assimilate food and excrete waste matter. Too much food adds an unnecessary burden, and food that is hard to digest wastes energy that is needed for defense and repair. For instance, meat soups do more harm than good, because they tax the kidneys enormously and yield almost no energy. Sugar in reasonable amounts is a valuable food in pneumonia, because it yields a great deal of energy and leaves nothing but water and carbon dioxide to be eliminated. Eggs and milk are very appropriate, but the stomach should not be overloaded even with these. The problem is rather the wise expenditure of the energy the patient already has on hand rather than to attempt to create new energy by forced feeding. In the average well-nourished individual there is a considerable supply of food already prepared in the body in the shape of fat, glycogen, and the tissue proteids, and these may be safely drawn upon for a few days. Air and water are absolute necessities for a man to win the fight, but a stomach too full may cause defeat.

Fright and worry are capable of killing a well person. Undoubtedly they are quite as important as pleurisy or pericarditis as fatal factors in pneumonia. Lack of sleep, especially if accompanied by restlessness, may result in exhaustion and death. If lack of sleep is caused by pain, morphine may save life. Fever is not generally a fatal factor in pneumonia. Only when fever reaches 105° or 106° is it doing harm, as a rule.

After thoroughly investigating the treatment of pneumonia in four of the largest eastern hospitals, the late Dr. H. P. Loomis[4] said, "I believe that if fewer drugs were given in pneumonia, a very much larger number of uncomplicated cases would recover with no medical treatment beyond an occasional laxative." He found the mortality in these hospitals to vary from 34.8 to 40 per cent. Dr. Deeks reports that on the Isthmus of Panama the mortality of 338 cases treated with quinine was 41.4 per cent., while the mortality of 236 cases treated without quinine was 30.5 per cent. The result was about 11 per cent. better without quinine. Might some other drugs be omitted with like improvement? Baginsky says that since he has come to treat pneumonia in children by ice bags for the pain, by hygienic measures, and no medicine, it has come to be the most successfully treated of all infectious diseases. Dr. Simon Baruch has lost no uncomplicated case of pneumonia since adopting his plan of cold packs to the chest, absolute rest, fresh air, cold water as a diuretic and drugs limited almost entirely to calomel, strychnine, and morphine. It is to be noted that Dr. Baruch draws his cases from the same region where the mortality of pneumonia is said to be from 30 to 40 per cent in the large hospitals. Dr. Thos. J. Mays reports a mortality of 3 per cent with his method of ice bags to the chest. M. Howard Fussell[5] says that since he has treated pneuomnia by absolute rest, wide-open windows and general hygiene, his medication has been practically nil and his mortality small. True, some report a very low mortality from the use of certain drugs, but, so far as my investigations go, they have been careful men who made wise use of rest, air, and water also. Generally speaking, it may be said that those who use few drugs and pay great attention to physiological measures have a much less mortality than those who concentrate their attention on drugs to meet every indication and neglect the teachings of physiology. Anyone who investigates will, I believe, reach the same conclusion as did Dr. Loomis, that indiscriminate drugging increases the mortality of pneumonia very much.

Failure to keep the patient continuously in the horizontal position adds greatly to the mortality of pneumonia. In my limited experience of about 200 cases, I have never seen recovery take place where the patient persistently got out of bed. The following is an illustration: June 17, 1909, I saw a Mexican laborer, about 25 years of age, who had been sick three days with lobar pneumonia. The upper right lobe gave dullness and bronchial breathing, the respiration was 32, the pulse 132, axillary temperature 104°. June 18, his respiration was 42, pulse 135, axillary temperature 104°. In spite of instructions, he had been getting up and going

from one bed to another because, as he said, he was too hot. June 19 I found him a block away from his house, sitting in the shade. His skin was covered with cold sweat, his lips and face were blue, he was gasping for breath, and his pulse was 170 and almost imperceptible. An hour later he was dead. Why is failure to maintain the horizontal position so disastrous? Because it overtaxes the circulation and wastes energy. We know that vasomotor paralysis is the chief cause of death in pneumonia. The vertical position makes such paralysis much more likely to take place.

Energy is expended in two principal ways in maintaining the circulation. The heart does work in pumping the blood, and the unstriated muscles in the walls of the smaller arteries and the nerves that supply them do a great amount of work in maintaining that constant, tonic contraction against the force of the heart which is necessary to maintain blood-pressure at the normal height. If the vessels of the portal circulation lose their tone and dilate, they are capable of containing about all the blood in the body. In fact, according to Howell[6], the vessels of the splanchoric area play a dominating part in the maintenance of normal blood pressure. Now, if we place the patient in the sitting position, these vessels of the splanchoric area have to maintain contraction, not only against the work of the heart, but, in addition, against the hydrostatic pressure of a column of blood, extending from the abdomen to the head, or about 60 grams per square centimeter. That would be over 40 millimeters of mercury; which means that by setting the patient up in bed we add about one-fourth to the work of the vessels in the portal system. It is easy to see that in pneumonia, with the vasomotor system already much weakened by toxemia, the addition of this needless hydrostatic pressure may readily cause paralysis of the vessels of the splanchnic area and death from circulatory failure. The higher mortality of pneumonia in women may be explained by the lax abdominal walls, which fail to maintain the intraabdominal pressure.

The horizontal position is advantageous in another way, for it saves the heart the work of elevating the blood to parts above its own level. Furthermore, we know that the toxin of pneumonia has a special tendency to paralyze the vasomotor center in the medulla. That is another reason why the head should be kept low, in order that the important centers in the medulla may receive an adequate supply of blood. The patient should be urged to lie as still as possible, for it is probable that muscular movement increases toxemia and raises temperature, just as it does in tuberculosis.

Rest is the principal thing in pneumonia, aside from air and water. If drugs are necessary to secure rest, they should certainly be used. If a patient cannot lie still on account of pleuritic pain, morphine may save life by enabling him to rest. A patient who can not lie down on account of dyspnea and incessant cough, due to early dilatation of the heart and beginning edema of the lungs, should be bled until he can lie down, and then given heart stimulants. Many mild cases of pneumonia are made severe because absolute rest in the horizontal position is not enforced from the very beginning, while the diagnosis is still uncertain. Every case of pneumonia, and every suspected case, should be put to bed and kept flat, with the limbs extended and the hips, shoulders and head on the same level, so as to make the circulation of the blood the easiest possible, both for the heart of the vasomotor system. Until this becomes the common practice, the mortality of pneumonia will never be as low as it should be.

The statistics of Wells,[7] covering 465,000 cases, showed a mortality of 20.4 per cent. Statistics made up by excluding fatal cases for one reason or another are valueless. The same is true if doubtful cases are included. Practically bronchial breathing and percussion dullness are the only certain signs of pneumonia, aside from laboratory diagnosis. Observing these precautions, my own mortality has been something less than 15 per cent. During the last year I have treated 32 cases of lobar pneumonia with 3 deaths. That is a mortality of less than 10 per cent. One of the fatal cases is reported above, one was in the last stages of aortic insufficiency, and the other was a woman about 70 years of age and a chronic asthmatic.

Of all fatal factors in pneumonia, lack of early, complete and continuous rest in the horizontal position is without a doubt responsible for more deaths than any other one thing.

A considerable mortality from pneumonia is inevitable. But the inevitable mortality is far less than what is occurring at the present time. In my opinion, much of the present mortality is needless. There is no serious infectious disease against which the body has more perfect means of natural defense. If only given a good fighting chance, a complete cure is generally effected in about 5 to 10 days without the aid (?) of any "specific" whatever. The body will take care of the pneumococcus if we take care of the body. The great fatal factors in pneumonia are, half enough water; half enough air; half enough rest; and too much meddlesome medication.

PSYCHIATRY AND THE GENERAL PRACTITIONER.

By PAUL B. BROOKS, M.D.,

Norwich, N. Y.

Formerly Member of the Staff of the Buffalo State Hospital for the Insane, Member of the Alumni of Bellevue Hospital, etc.

Knowledge of psychiatry has been accumulating so rapidly during the past few years that it has been nearly an impossibility for the busy general practitioner to keep abreast of the change. As a consequence, psychiatric science finds little application in his practice. He deals with the less active psychoses, when they complicate his cases, as best he can by applying his knowledge of general medicine; while the actively insane patient is hustled off to an institution as soon as the committing physicians can gather enough data to convince a magistrate of the mere fact of insanity. The reader will find nothing new or original in the subject matter which fol-

lows. But he will have his attention directed to the fact that there is much in the new psychiatry which is both interesting and an essential addition to his medical knowledge, if he would practise medicine intelligently. The subject is presented, not from the standpoint of a psychiatrist, but of a general practitioner.

A little study on the part of the men who have had little interest in the subject will reveal the fact that, largely within the past two or three decades, it has been removed from a purely empirical to a scientific basis.

The general practitioner is the first to see cases of mental disorder. Perhaps he assisted the patient over the devious route which brought him into the world. He is cognizant of much in the history that would be of value to the psychiatrist, who attends the patient later, and which the latter may fail to elicit through the usual channels for history geting.

Unfortunately, many general practitioners underrate the importance of accurate and early diagnosis and prompt and properly directed treatment in cases of insanity. This is due, probably, to the fact that they received their instruction in the not very remote days of empirical psychiatry, when the diagnosis of insanity having been made, an unfavorable prognosis was more than likely to follow. Today all this is changed. Under the present régime of rational diagnosis and treatment, in which restraint plays little part, recovery occurs in a liberal percentage of all acute cases admitted to State hospitals, and in many of the less acute; and the earlier in the course of the disease the patient is admitted to the institution, the better the outlook for early recovery. This fact, amply borne out by statistics, speaks well for the treatment such patients receive in the institutions. To what extent, if any, unintelligent treatment outside the institutions may be a factor in making this true, I am not prepared to say.

Appreciating the advantage, to both, of cooperation between institutional and family physician, the medical men in charge of the New York State Hospital system have recently undertaken an innovation, which we, as general practitioners, should appreciate. At least twice each week it has long been customary for the staff of each hospital to meet for the discussion of cases of recent admission. I have not said "of interesting cases" because, in the light of modern methods of study, it seems that very few cases are wholly without interest. Histories, mental and physical examinations are worked up with a thoroughness and attention to minutiæ almost unknown in the average general hospital. The cases are discussed from the standpoint of diagnosis, treatment, and prognosis. Of late, invitations have been issued to the physicians who committed each patient presented at "staff meeting" to be present, listen to, and take part in, the discussion. The writer has had the pleasure of attending but one such meeting in his capacity of committing physician, but he found that it was well worth all the time and energy spent in the forty-mile trip to the hospital.

As for the institutions in which our insane are cared for, it is a far cry from the County House of twenty or thirty years ago, where patients were "cared for" by being confined where they could not harm others or disturb the public, through the "asylum" stage, to the present system of thoroughly equipped and intelligently conducted hospitals for the insane. Not only are patients examined and case records filed with the utmost thoroughness, and skilled attention given to the treatment of physical as well as mental conditions, but of late physicians from the hospitals have been visiting the homes of patients recently admitted, to investigate their environment, with a view to improving it, if necessary, when the patient is in condition to leave the institution.

The classification of insanity has always been difficult and unsatisfactory at best. For the sake of comparison, there follows the classification adopted for statistical purposes by the State Commission in Lunacy in 1897, and after it, that adopted by the State Commission recently, for the same purpose. It will be noted that with the first it was necessary to cut diagnoses to fit the classification. In the latter, the conditions which cannot consistently be given a place in any of the established groups are frankly designated as "allied to" certain groups or as "Unclassified," although the necessity for falling back on these captions is daily growing less. In giving the new classification, I have quoted freely from the pamphlet recently issued to the New York State Hospital physicians.

Classification adopted in 1897:

Mania, acute delirious; mania, acute; mania, recurrent; mania, chronic; melancholia, acute; melancholia, simple; melancholia, chronic; alternating (circular) insanity; paranoia; general paralysis; dementia, primary; dementia, terminal; epilepsy with insanity; idiocy.

Classification recently adopted:

1. Psychoses with brain tumor.
2. Traumatic psychoses.
3. Senile psychoses.
4. Dementia paralytica; (a) cerebral form, (b) tabetic form to diminished or absent knee-jerks), (c) mixed form.
5. Psychoses with other brain and nervous diseases; (a) cerebral syphilis, (b) cerebral arteriosclerosis, (c) cerebral embolus or hemorrhage, (d) brain abscess, (d) tuberculous meningitis, (e) central neuritis, (f) multiple sclerosis, (g) polyneuritis, (h) tabes dorsalis, (j) acute chorea, and other nervous affections.
6. Alcoholic psychoses; (a) pathological intoxication, (b) alcoholic deterioration, (c) delirium tremens, (d) Korsakow's disease (polyneuritic psychosis), (e) acute hallucinosis, (f) chronic hallucinatory type, (g) paranoid states; (1) acute delusional type, (2) chronic delusional type, (3) delusion of jealousy; (h) other less characteristic symptomatic types.
7. Drug and toxic psychoses.
8. Infective-exhaustive and autotoxic psychoses; (a) infective or exhaustive reactions; (1) febrile delirium, (2) infection delirium, (3) exhaustion delirium (acute confusion, hallucinatory delirium, "amentia"); (4) delirium, with heart disease, (b) autotoxic disorders. (1) Thyrogenous disorders, (2) uremic and diabetic disorders.
9. Allied to infective-exhaustive type.
10. Symptomatic depressions; depressions closely associated with some physical ailment which more or less naturally predisposes to despondency.
11. Depressive hallucinosis; depressions usually of acute onset, in which hallucinations (generally auditory) dominate the scene, the sensorium remaining clear, the mood being one of anxiety or fear.

12. Involution melancholia; agitated depressions of middle life and later years, developing after prolonged worrying and uneasiness, with fretting and insomnia.

13. Depressions undifferentiated.

14. Dementia præcox; (a) paranoid form, (b) catatonic form, (c) hebephrenic form, (d) simple form.

15. Allied to dementia præcox.

16. Paranoic conditions.

17. Manic depressive phychoses; (a) manic attack, (b) depressive attack, (c) circular attack, (d) mixed conditions.

18. Applied to manic depressive psychoses.

19. Epileptic psychoses; (a) deterioration, (b) dazed states, (c) anxious delirium, (d) excitement, (simple or hallucinatory.)

20. Hysterical, psychasthenic, and neurasthenic psychoses.

21. Other constitutional disorders and inferiorities. A variety of types fall under this general heading. A satisfactory classification is not yet possible, but as provisional clinical groups one may contrast two types: (a) Constitutional psychopathic states. These individuals are usually well endowed intellectually, or at least are superficially bright, but they show lack of emotional balance, weakness of judgment, and undue suggestibility, which traits are often combined with defects of character or perversion of instinct. On this psychopathic basis various episodes may occur and necessitate commitment. (Excitements, depressions, paranoid trends, hallucinatory attacks, etc.). (b)) Constitutional inferiority; intellectual deficiency of a mild degree, to which may be added neurotic traits, signs of emotional instability, or moral defects. Transitory attacks of excitement or depression, paranoid states, and hallucinatory episodes may develop in these constitutionally inferior persons.

22. Imbecility with insanity.

23. Unclassified.

If the newer classification is more complex, it is also more satisfactory, for it is obvious that only with such a classification can any attempt be made to intelligently dispose of all the prevalent mental diseases. It has been adopted largely through the efforts of an eminent scientist and psychiatrist, Dr. Adolf Meyer, for several years and until recently, the moving spirit in the scientific work being done by the physicians of the New York State Hospital service. It is an adaptation of the classification which has been advocated by Kraepelin, of the German school.

In comparing the new with the old, one condition stands out preeminently as a product of modern psychiatry. In dementia precox the general practitioner, and the psychiatrist as well, finds much that is hard to master. Perhaps I can best quote a well-known writer: "Dementia precox is the name provisionally applied to a group of cases which are characterized in common by a pronounced tendency to mental deterioration of varying grades. Dementia, fortunately, does not occur in all cases, but is so prominent a feature that the name is best retained until the symptom group is better understood. The disease is one of the most prominent, comprising from 14 to 30 per cent. of all admissions to insane institutions. More than 60 per cent. of the cases appear before the twenty-fifth year." And again: "The disease, in the younger cases, seems to take the form of a simple, gradually progressive deterioration; in the somewhat later periods it assumes the acute or subacute forms with catatonic symptoms; while still later the more pronounced delusional formation appears." There are, however, no hard and fast rules to which we can cling, and the disease presents many variations. Until recently, the prognosis has been looked upon as invariably unfavorable as to recovery, but recent developments, I believe, have cast some doubt upon the wisdom of making a bad prognosis in every case. Dementia præcox has absorbed the primary dementias of the older classifications.

The manic depressive psychosis is a composite of the various manias, most of the melancholias, and the circular insanity of the old classification. It has been found that these are but varying phases of the same general condition.

In a paper of this scope, we are not justified in going over the long list of psychoses. So, in conclusion, the writer would take the opportunity to urge a more effective cooperation, reacting to the advantage, both of the general practitioner and of the psychiatrist to whom he sends his cases. The writer is almost inclined to offer, for the consideration of the State Hospital physicians, the suggestion that they institute a series of clinical lectures, for instance, one a month, upon the rudiments of the new psychiatry, for the benefit of the physicians in their districts. Such a course would result in more intelligent prophylaxis and after-treatment, more satisfactory commitment papers, and would create a more thorough cooperation and more sympathetic personal relations between the physicians in institutional and those in private work. While I am told that the physicians, so far, have not responded, to any great extent, to the advances already made, in the way of invitations to attend staff discussions, this is undoubtedly because we general practitioners are slow to adopt innovations, and moreover, little is generally known regarding the character and excellence of the work being done in the State institutions. A visit to one of the State hospitals, with an inspection of the pathological laboratory and museum, therapeutic equipment, etc., would result in a revelation to some of my fellow practitioners.

If the suggestion made above is impracticable, we can at least issue urgent invitations to some of the medical officers of our neighboring hospitals to attend county society and other medical meetings and to tell us as much regarding the new psychiatry as limited time will permit.

To summarize, the study of mental diseases has progressed so rapidly in the past few years that the general practitioner has fallen behind. This paper is presented with the hope of stirring renewed interest and more effective cooperation with the specialists in psychiatry in our State hospitals for the insane. An old and a recent classification of insanity is presented, for comparison, as showing the great advance in knowledge of mental diseases. One condition, dementia precox, seems to be attracting more attention just now than any of the others. The writer heartily recommends that his fellow practitioners take advantage of the invitations to attend staff meetings at the State hospitals, and that they seek the assistance of the hospital physicians to enable them to become more thoroughly acquainted with the new things in psychiatry, feeling that it will prove a diversion, and perhaps make them better practitioners.

SOME ANOMALIES AND POINTS FOR THE SURGEON TO BEAR IN MIND.

By CHARLES F. DISEN, M.D.,

DEMONSTRATOR OF ANATOMY, STATE UNIVERSITY OF MINNESOTA.

In the dissecting room anomalies seem to appear in lots, although it may be averred that, if looked for they would be found with some measure of regularity. Thus, taking the kidney for an example, I find, on reviewing my anomaly charts for the last 20 bodies dissected, six rather important anomalies. Another lot of 20 bodies might not furnish other anomalies of that organ than aberrant arteries entering beyond the hilus, such arterial anomaly seeming to occur much more frequently than is generally assumed.

Describing the six important anomalies, the first one to be given is a horseshoe-kidney. It was huge, occupying a large part of the abdominal cavity. The convexity was turned downwards, both ureters as well as the spermatic and inferior mesenteric vessels crossing the ventral surface of the mass. At the middle of the inferior border of the convexity an accessory vein passed off to enter the left common iliac vein, reminding one of the caudal vein that in some lower animals enters the kidney. The second case is presented by an infant, in which the inferior vena cava takes a curve into the hilus of the right kidney. This instance reminds us of the fact that more than one life has been lost on the operating table—and in the hands of distinguished surgeons—by interference with the vena cava in ligating for extirpation of the right kidney. In the third case one kidney has two ureters, separate as far as the opening into the bladder. The fourth case has three arteries given off separately from the aorta to each kidney. The fifth case has four arteries also given off separately as individual trunks from the aorta to each kidney. In both instances the uppermost and the lowermost artery entered the extreme upper part of the upper pole and the extreme lower part of the lower pole, respectively. The sixth case, perhaps of interest only for its rarity, has the left renal vein behind instead of in front of the aorta. Some of these anomalies certainly indicate that, whenever possible, the kidney should be cautiously inspected before ligating in the operation of nephrectomy. In this connection it may be of interest to the surgeon who, in exposing the kidney by the lumbar route, counts the layers of lumbodorsal fascia—as guide and with the view of guarding the nerves—to note that some modern textbooks only describe two layers. They ignore the layer in front of the quadratus lumborum, but, going by my own experience, I must say that it seldom fails to exist.

Considering operations on the bile-ducts, the surgeon should not take for granted that the structure, found at the extreme edge of the lesser omentum, always is the common duct. In the proportion of about one in fifteen bodies a quite large artery is lying parallel in front of the bile-duct. Sometimes it is the superior pancreatico-duodenal artery that takes this upward course to the gall-bladder, instead of descending to the pancreas and duodenum. At other times the inferior pancreatico-duodenal artery was found to take a similar course. It may not be amiss to mention that the portal vein sometimes has a very thin wall, and when in addition, as in case of the drinker, fatty degeneration happens to be present, this vein does not stand much handling. I know at least of one instance where the surgeon ruptured it in hooking his finger too forcibly forward in the foramen of Winslow. The result was fatal.

Occasionally the existence of a ligamentum cystoduodenale or hepatocolicum is responsible for a lateral extension of the lesser omentum, far beyond the place occupied by the bile-duct.

Considering thyroidectomy, I have investigated the relation between the recurrent laryngeal nerve and the inferior thyroid artery, as the operation so frequently is followed by aphonia, although, as a rule, only of a temporary character. The relation is not a fixed one; the nerve may be found either behind or in front of the artery, sometimes being split and going partly behind, partly in front of the vessel. In a good proportion of cases the nerve is behind the vessel on one side of the neck and in front on the other side, without maintaining any rule for either side. The advice of the Drs. Mayo to clamp the vessels in a vertical direction is certainly opportune; the chance of including the nerve is thus minimized, however more so on the left side, where the nerve has a more vertical course than on the right side. Regarding the parathyroids, they are not always found to be distinctly apart from the thyroid; frequently they are matted to the latter, if not actually imbedded. In the dissecting room they are recognized by having a more yellowish or lighter color than the thyroid, and as imparting on touch the idea of a finer structure. In spite of diminutive size and of the claim by some that they are embryonic forms of thyroid, it seems that the parathyroids, as furnishing an important special internal secretion that operates on the nervous system, are indispensable organs even to advanced age, and it follows, as generally settled, that they always should be saved. Simply leaving some thyroid tissue, unless it be connected with the parathyroids, is inadequate, as experiments on animals have repeatedly taught that the thyroid does not vicariate for the parathyroid. On the other hand, it is of scientific interest to note that some observers have found that the parathyroid begins to resemble the thyroid histologically three months after removal of the latter.

In ligation of the external carotid artery it easily happens that the hypoglossal nerve becomes cut in the incision, and recently a prominent surgeon was heavily sued for such an accident. In my own work I find the only safeguard is to locate the nerve by hunting in the angle between the greater cornu of the hyoid bone and the posterior belly of the digastric muscle, before I look for the artery. Similarly, in ligation of the third part of the subclavian artery, it simplifies the operation much if the posterior belly of the omohyoid muscle is located and it be remembered to incise a second layer of deep cervical fascia—the lateral extension of the prevertebral—before the vessel is sought at the lateral border of scalenus anticus. The arm must be continuously drawn downward, partly in order to displace the suprascapular artery. The right common carotid artery may be found overlapped by the internal jugular vein, although the textbooks only credit the left carotid with such, an at least occasional, relation.

Regarding the upper extremity, the only anomaly I can think of that might embarrass the surgeon is high division of the brachial artery. Sometimes I notice three specimens of this anomaly in one term; then, again, it may not put in an appearance for some three or four semesters.

In operating for femoral hernia it should be remembered that the femoral vein may not be covered with fascia lata in the region of operation; a fatty layer instead, an unusually extensive cribriform fascia, may have taken its place. To my knowledge the textbooks do not mention this occasional arrangement; it may be excusable if fatty change in the iliac portion of the fascia lata is a responsible factor, but it does happen that the surgeon cuts the femoral vein, because he is not familiar with this occasionally changed relation of the vessel. While on hernia, it may be stated that the interfoveolaris muscle described by some modern text-books in connection with the insertion of the conjoined tendon, which some surgeons imagined could be utilized to strengthen the inguinal canal, seldom exists, and, if present, is too frail for such a purpose.

In conclusion I wish to report an anomaly, or rather a rare excursion of the sigmoid colon. Instead of curving downwards from the descending colon to the bottom of the pelvis, it ascended as high as the upper part of the psoas muscle, where it was held by a short mesocolon; thence, it curved downwards to become the rectum. The specimen reminds me of the case of a female patient who presented a tumor-like mass in the abdomen, appearing in shape and size as a uterus in the seventh month of pregnancy. Consultants diagnosed fibroid tumor and set a day for operation. When temporizing with enemata the tumor disappeared. It may easily be guessed that impaction in a sigmoid loop, arranged as the one just given, would be liable to furnish such an embarrassing condition for diagnosis.

HEMORRHAGE AFTER REMOVAL OF TURBINATED BODIES.

By JULIUS SOLOW, M.D.,

BROOKLYN, N. Y.

Hemorrhage after operation on the faucial tonsils or adenoid tissues is very frequent, as everybody who occupies himself with this special work knows, but it is not so frequent as that which we often see after the removal of turbinated hypertrophies. The hemorrhage, after removing any of the turbinated hypertrophies, lower or middle, may be only slight, and in this case it can be stopped by introducing a tampon of absorbent cotton into the nasal cavity and changing it a few times till the flow of blood ceases. In other cases again the hemorrhage may be very profuse and obstinate. Even cases in which only a small portion of a turbinated hypertrophy is clipped off, may have a severe postoperative bleeding. So, for instance, in the case related to me by Dr. Wolff Freudenthal of this city, in which he only removed a small portion of the middle turbinated body, and this was followed by a severe hemorrhage six days after the operation.

In persistent and severe hemorrhage it is always advisable to apply ice externally to the bridge of the nose and introduce into the nasal cavity a tampon of absorbent cotton soaked with adrenalin solution (1:1000), or with suprarenal extract (5 per cent.). In hemorrhages coming from the region of the middle turbinated bodies, the employment of aseptic gauze would be more advisable. Some advise the introduction of small pieces of ice into the nostril, but I think we can get along easily in most cases with only external application of ice and tamponading of the nasal cavity. When, after a severe hemorrhage, we succeed in stopping the flow of blood, then we leave the tampon in for about two days without disturbing it, as any attempt to remove the tampon before that time may be followed by a fresh bleeding. But after that the bleeding vessel is usually closed by a substantial thrombus and it is then safe to change the tampons. Should any difficulty arise in removing the tampons, it is advisable to irrigate the nares very carefully with a mild antiseptic solution. Total packing of the nose with sterilized gauze, anteriorly and posteriorly, is advisable only when all other means of stopping the hemorrhage have failed.

Septic complications, affections of the eustachian tube and the accessory sinuses of the nose, through retained discharge, are rare, unless the tampons are left in too long. Such complications, however, are frequently met with in cases where we are compelled to pack the nose completely. If the hemorrhage is not too severe, a tampon of asborbent cotton, soaked with a strong solution of tannic acid, may also do the work. Some use hot water irrigations in order to stop the bleeding. Its effect is the same as in hemorrhages of the uterus. But the water must be pretty hot in order to have any effect. Peroxide of hydrogen is also used considerably.

The one great advantage we have in being nearly always able to get control of the bleeding in such cases is that we always know where to look for the exact source of the bleeding, while in nose bleed from other causes, not post-operative, the exact source of the bleeding is not always known to us.

78 McKibben Street.

Epidemic Icterus.—Queirolo has studied an epidemic of icterus which occurred two years ago in Portoferraro, and repeated the observations in a similar epidemic at Piombino. The same conclusions are given as a result of the two different epidemics. Contrary to the affirmation of Chauffard, the malady can be imported and disseminated by the patients. The malady seems to be of telluric origin, the poison arising in hot, damp places where there is an excess of organic materials, is carried about by winds and by the patients themselves. The malady is especially dangerous to pregnant women, ten out of twelve affected having died at Piombino. Death occurred with symptoms of a profound intoxication, with the syndrome of hepatic coma. This poison has an especial action on the liver in women, who during pregnancy have inactive livers, the effect being to paralyze the depurative function of the organ. The renal and liver lesions of acute yellow atrophy are absent at autopsy. In some cases the production of premature labor has been of benefit to the patients in pregnancy.—*La Riforma Medica.*

Treatment of Osteomalacia by Adrenal Extracts.—Leon Bernard believes it necessary to the gaining of a sufficient knowledge of the action of adrenal extracts in osteomalacia that all cases should be reported in which it has been used. He reports a case of osteomalacia in a woman of 38 years of age, who was unable to leave her bed or to move any of her limbs except the left arm, on account of the pain produced and the existing deformities. She had, at the age of sixteen, an attack of the same disease, which was finally recovered from by rest in bed for a year and a half. She had amenorrhea at that time, and improvement began with the return of the menses. She remained well for ten years, at the end of which time she had a renewal of the disease, which brought her to a pitiable condition, sleepless and in constant pain, with marked deformities. Injections were given subcutaneously every two days. After thirty injections, marked improvement began. At the end of 100 injections she was entirely restored to health, could walk, go up and down stairs, and sleep well. Pain was gone and all deformities had passed away. The process had stopped and the bones had cicatrized. As to the cause of this action of adrenalin, the author believes that it is not due to the power of the drug to hold lime in solution in the organism. There seems to be a sort of antagonism between the actions of the ovaries and the suprarenal glands. Probably the curative action is due to opotherapy. —*La Presse Médicale.*

THE PROBLEM OF MILK SUPPLIES.

Perhaps one of the most complete and instructive reports on the milk question ever issued has been published recently by the Ontario Milk Commission. This commission was appointed by the Ontario Legislative Assembly to inquire into the production, care, and distribution of milk in all parts of the immense province of Ontario, and right thoroughly and well have the members thereof done their work. Of course, much of the ground gone over—that is, in discussing and summing up the general situation as regards milk—has been traversed oftimes before, and necessarily, too, many, if not most, of the conclusions arrived at have been reached by former writers, practical workers, and commissions. However, nothing but good can come of the intelligent study of the milk question, and the more frequently and the more fully the matter is ventilated publicly, the sooner will come the much-needed reforms. It is to be gathered from the report of the Ontario commission that many of the citizens of the large and small towns of Ontario have been living more or less in a fool's paradise with respect to their milk supply. Whether the dairy farmers and dealers have been living in a similar paradise is to be doubted, or even possibly it may be doubted whether many of the citizens have not been suspicious of the quality of the milk. However this may be, the report renders clear to all that in order to obtain a passably pure milk supply in Ontario, reforms are urgently needed.

The infant mortality rate in Ontario is extraordinarily high for a sparsely populated district. The death rate under one year per 1,000 births for Ontario, according to the latest census, was over 160, while for Toronto it was more than 175. When the fact is taken into consideration that the death rate for infants in London, with its manifold slums, is only 116 per 1,000 births, the significance of the figures for Ontario will be better appreciated. The report holds the inferiority of the milk supply mainly responsible for the untowardly high infant mortality rate, and without doubt rightly.

The following are the conclusions reached by the Ontario Milk Commission: 1. The present laws governing the production, care, and distribution of milk for human consumption are cumbersome and ineffective, and should be consolidated and amplified. 2. The general principles governing the production, care, and distribution of milk should be fixed by the Legislature. 3. Inasmuch as the administration of such laws is and must remain in the hands of municipalities, such amplification should be in the direction of giving municipal authorities larger powers of licensing and supervision. 4. A general definition of adulteration should be adopted, but municipalities should be given the power to fix a standard of food value, said standard to be not less than 3 per cent. butter fat and 12 per cent. solids. 5. In the interests of health and common decency, more attention should be paid to the cleanliness of stables and healthfulness of cattle, and to this end the consuming municipalities should be empowered to make inspections at the sources of supply and be urged to appoint veterinarians to act in conjunction with the medical officers of health. 6. With a view of lessening the alarming infantile mortality in the province, municipalities should be empowered to establish and maintain, or to assist in the establishment and maintenance of infants' milk supply depots. 7. Firm measures should be taken to combat the ravages of tuberculosis, which constitutes a serious menace to both bovine and human species; and as an initial step along with an educational campaign, all cows suffering from tuberculosis of the udder or showing clinical or physical evidences of the disease, or whose milk is shown by bacteriological or microscopical examination to contain tubercle bacilli, should be promptly removed from dairy herds. 8. Pasteurization is not a provincial ideal, but may be a municipal expedient if carried out in accordance with proper scientific regulations. 9. In cities of over 50,000 population no milk should be sold except in bottles or other sealed packages. 10. Cans, bottles, or other utensils used in handling milk should be used for no other purpose, and should be promptly rinsed by the consumer on being emptied. 11. Producer, distributor, and consumer should alike be educated to the importance of cleanliness in handling milk and to the value of prompt chilling and keeping in a cool place. These recommendations are exhaustive and, if carried out, would solve to a very large extent the difficulties of the existing situation in regard to the milk supply of Ontario. Unfortunately, these cannot be carried out in their entirety and the best that can be hoped is that the most important recommendations will be put into effect.

The recommendation of the greatest moment to the community at large is that which discusses tuberculosis in cows. Tuberculosis is prevalent among the milch cows of Ontario, and although there is no agreement as to the percentage of tuberculous animals, it would be no exaggeration to state that 10 per cent. of the dairy cows suffer from tuberculosis. There is no need here to enter into the vexed question of the transmissibility or otherwise of bovine tuberculosis to the human being. It is now generally believed that, given favoring conditions, tuberculosis can be, and is, frequently conveyed to young children by means of infected milk. Thus it is obvious that in Ontario the tuberculous cow is a grave

menace to health and life and that steps taken to abolish the diseased animal or to render it harmless will be steps taken for the benefit of the whole population of the province. The obstacles in the way of effective measures in this direction are very great, greater than in most districts, for the reason that farmers in Ontario hold the balance of political power, and they are not likely to enact laws which they imagine might be against their interests. Before the farmer will allow such legislation to be passed, he must be convinced that it is not opposed to his material welfare. Therefore the entire community must first be educated to comprehend that laws in support of a pure milk supply are beneficial to all, although in the first instance they may appear hurtful to some. The weight of opinion in towns and cities will settle the question, for the dairy farmer must supply the article for which his customers call. But in Ontario as elsewhere public opinion is not generally sufficiently well educated on the subject of milk, and it behooves the medical profession to instruct the laity as to the superlative necessity of an unpolluted milk supply. The Milk Commission of Ontario has taken New York City and some other cities in this State as models when studying the milk question, and it is to be hoped that much valuable information has been gained and that the knowledge will be not only assimilated but improved upon.

REPORT OF THE SURGEON-GENERAL OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

Good wine needs no bush, nor does the work of the Public Health and Marine-Hospital Service need commendation. But although the work does not need praise, at the same time it is both interesting and instructive to review the more important investigations and researches conducted by the members of the service during the year. As is well known its duties are manifold and far-reaching, and it is a matter of some difficulty to select any outstanding series of investigations and researches as worthy of special comment. Moreover, the more noteworthy features of the year's work have already been discussed in these columns.

One of the chief benefits rendered the community by the officers of the Service has been the abolition of plague from San Francisco. In Oakland, in Contra Costa County, in Point Richmond, in Alameda County, and in Los Angeles, anti-plague operations have been and are being prosecuted vigorously, with eminently satisfactory results, although it is stated that in the cities of Alameda and Berkeley antiquated methods of garbage and refuse disposal are still employed and rat destruction and other precautionary measures have been entirely neglected. On the whole, however, the State and local health officials of California have loyally cooperated with the officers of the Service. It is worthy of notice that in Contra Costa County 3,826 ground squirrels have been examined bacteriologically, of which number 42 were found to be infected with *B. pestis*.

The division of scientific research of the Service has been especially active during the year. The laboratories now in operation are the hygienic laboratory in Washington, the leprosy investigation laboratory in Hawaii, and the federal plague laboratories in San Francisco and Seattle, as well as small clinical laboratories at the Marine Hospital Sanatorium, Fort Stanton, N. M., and at certain of the marine hospitals. At most of these stations research work is being carried on. It is stated in the report that there is necessity for a research laboratory on the Gulf Coast for the investigation of tropical diseases and that a research laboratory should also be established in the region of the Great Lakes for the study of problems in relation to interstate sanitation, such as the prevention of the pollution of streams and the prevention of the transmission of typhoid fever, tuberculosis, and other communicable diseases by vessels and trains. Lastly, it is thought desirable that a research laboratory be established in New York, in which to investigate the problems arising through immigration, and in order to utilize the large amount of clinical material in the study of communicable diseases.

Perhaps the most important investigation undertaken by the department during the year has been that of typhoid fever in the District of Columbia. The conclusions reached have been fully dealt with in the editorial pages of the Medical Record, but it may be said that no more valuable studies as to the cause of typhoid fever have ever been conducted in America, and that with regard to human typhoid carriers as a means of spreading the disease, fresh light has been thrown on the subject by the aid of which we must revise to a considerable extent our long-held views of the origin and spread of the disease. Pellagra has received the notice that its increasing prevalence or recognition deserves. On account of the widespread occurrence of amebiasis on the Pacific coast and in other parts of the country, it is expected to continue investigations of the disease at certain hospitals of the service to determine whether amebas can be found in the stools of patients suffering from intestinal and liver diseases, and to record and report on the antecedents of all cases of amebiasis. Leagues have been formed in the Southern States among the negroes, mainly in connection with the churches, to combat the ravages of tuberculosis. The bureau is assisting this movement by advice and by providing lectures to organize an educational campaign. The bureau suggests to the Federal Government, that in view of the prevalence of typhoid fever among negroes, due to ignorance of sanitary laws, it would be judicious to disseminate information as to the necessity of proper sanitation, better educational facilities, and more recreation, and the means necessary to bring these reforms about.

So far as domestic quarantine was concerned, during the fiscal year ending June 30, 1909, at the various stations of the United States, a total of 8,266 vessels were inspected by officers of the service, and under their supervision 520 were disin-

fected, either for the destruction of mosquitos as a precaution against the introduction of yellow fever, or for the destruction of rats and other vermin as a precaution against plague. In addition 495 vessels were spoken and passed, making a grand total of 8,761 vessels passing under the observation of the service at the ports in the continental United States. The operations of the service as to quarantine in the Philippine Islands is stated to have been remarkably effective, while similar statements apply to Hawaii and Porto Rico. The work of the service with respect to foreign quarantine covers a very wide field. The most unhealthy station with which the service was concerned was Guayaquil, Ecuador, in which city during the year there have been outbreaks of plague, smallpox, and yellow fever. An idea of the unhealthfulness of the locality may be gathered from the fact that the annual death-rate varies from between 25 and 30 per thousand in July and August to between 90 to 100 per thousand in February and March. During the fiscal year ending June 30, 1909, 966,124 immigrants were examined by medical officers of the service to determine their physical fitness for entrance at ports in the United States and in Porto Rico and Hawaii. During the year 53,074 seamen were treated at the various stations of the service. The service operated 21 hospitals and maintained 126 other stations. The results of treatment of cases of tuberculosis at Fort Stanton were satisfactory, but the medical officer in command points out that Fort Stanton being at an elevation of more than 6,000 feet certain classes of patients are not benefited by sojourn there.

Surgeon-General Wyman concludes the report by discussing certain public health problems in an interesting manner. A perusal of the entire report demonstrates the fact that the officers of the service are, as always, fully alive to the importance of their duties and lose no opportunity to conserve the health of the American people. The service deserves in a high degree the confidence of the nation and should be rewarded in a correspondingly generous manner.

Hookworm Disease or Ground Itch Anemia Among Public School Children.

Dr. Chas. Wardell Stiles of the Public Health and Marine-Hospital Service publishes in Public Health Reports, March 25, 1910, the result of some observations made by him in February last with regard to a number of school children in Southern Florida examined for hookworm disease. Together with Dr. E. E. Lindemann and Dr. J. S. Helms eight schools were visited and 1,306 children inspected. The pupils were classified as "suspects," "doubtfuls," and "non-suspects," and the following is a summary of the outcome of the examination: Boys, 596—number of suspects, 409; percentage of suspects, 68.6. Girls, 710—number of suspects, 322; percentage of suspects, 45.3. Total, 1306—number of suspects, 731; percentage of suspects, 55.9. Those classified as suspects were obviously suffering from hookworm disease, and Dr. Stiles thinks that according to experience, on a basis of 55.9 per cent. suspects, it may be concluded that the infection is probably not less than 80 per cent. It may also be pointed out that the pupils in these schools represented not only some very poor children from the farms, but also children of very well-to-do families from farms and towns. Furthermore, at least five of the teachers in the schools visited showed clear and pronounced effects of hookworm disease. The observations referred to above only go to show that which is already well known to physicians in many of the Southern States that hookworm disease is lamentably common among the general population and that the sooner the work of the Rockefeller Commission is earnestly undertaken the better it will be for all concerned. Certain skeptical individuals have gone out of their way to sneer at the philanthropy of the millionaire and to suggest that the money donated might have been more usefully spent otherwise. All evidence shows that a crusade against hookworm disease is urgently called for in parts of the Southern States. Dr. Stiles draws attention to a somewhat amusing difficulty which has arisen as to the treatment of sufferers from hookworm disease. They refuse to consider treatment if they are told that they have hookworm disease, but willingly undergo the same if the complaint is termed uncinariasis, or even if alluded to by the plebeian name of "ground itch." The possession of hookworm disease they regard as something of a social slur.

The Germicidal Action of Water from Coal Mines and Tanneries.

In the Pennsylvania Health Bulletin, November, 1909, the above subject is considered and discussed. Experiments were undertaken at the laboratories of the Pennsylvania State Department of Health, under the direction of Dr. Samuel G. Dixon, to discover the influence of water from coal mines and tannery wheels upon certain pathogenic bacilli. It has been observed that the water supplies of cities situated on main streams, below extensive coal fields in Pennsylvania, such supplies being drawn from these streams, are comparatively free from bacterial life in spite of the large quantities of sewage deposited therein. This freedom from germs is attributed to the action of the acid drainage from the mines. Spent tan liquors from tanneries are known to exert a somewhat similar influence on sewage organisms. The conclusions reached as a result of the experiments were as follows: Mine water will prevent the growth of typhoid bacilli after the lapse of one hour. Mine water will markedly limit the growth of colon bacilli so that they die off progressively and cannot be cultivated after a lapse of twenty-four hours. The organisms lived for three days but could not be found on the fourth day in one experiment in which the dilution was high. Spent tan liquor limits the growth of the typhoid bacillus and causes it to disappear after the sixth hour. Tan liquor permits the growth of the colon bacillus up to the twenty-fourth hour and in one experiment where the dilution was 1-4000 it was found after three days. The tan liquor has a somewhat similar effect on *B. anthracis* as on *B. coli*. The inference which Dr. Dixon thinks should be drawn from these experiments is that, so far as the risk of the most serious of all water pollutions is concerned, judging by the typhoid bacillus and its companion and index, the colon bacillus, and inferentially the cholera bacillus, which is known to succumb readily to sulphuric acid, the attempt to exclude mine water and spent tan water from streams which may eventually become sources of

drinking water would be a mistake. The opinion has long been held by those who have studied the health conditions of Philadelphia that the acid condition of the head waters of the Schuylkill River, owing to mine drainage, was an important factor in holding in check the prevalence of typhoid fever in that city. Dr. Dixon says that the results of the Pennsylvania Health Department experiments indicate that this opinion has a solid foundation.

News of the Week.

Army Medical Corps Examination.—The surgeon-general of the army announces that preliminary examination of applicants for appointment as first lieutenants in the Army Medical Corps will be held on July 18, 1910, at various army posts throughout the country. Full information concerning the examination can be procured upon application to the Surgeon-General, U. S. Army, Washington, D. C. The applicant must be a citizen of the United States and between 22 and 30 years of age. There are at present 123 vacancies in the Medical Corps of the army.

Medical Interne Government Hospital for the Insane.—The United States Civil Service Commission announces an examination on June 15, 1910, to secure eligibles from which to make certification to fill at least two vacancies in the position of medical interne (male), Government Hospital for the Insane, Washington, D. C., at $600 per annum each, with maintenance, and vacancies requiring similar qualifications as they may occur in that hospital, unless it shall be decided in the interests of the service to fill either or both of the vacancies by reinstatement, transfer, or promotion. Both men and women will be admitted to this examination, although there are no vacancies for women at present. Applicants must be unmarried. Age limit, 20 years or over on the date of the examination. Applicants should at once apply to the United States Civil Servic Commission, Washington, D. C., for application Form 1312. No application will be accepted unless properly executed and filed with the Commission at Washington.

National Tuberculosis Sunday.—The National Association for the Study and Prevention of Tuberculosis has set aside Sunday, April 24, as a "National Tuberculosis Sunday" on which all clergymen are asked to preach on the subject: No Uncared for Tuberculosis in 1915. Under the direction of the head of the Labor Department of the State Charities Aid Association, the labor unions of the large cities are being requested to attend church in a body on that day, or to have the subject of tuberculosis discussed at their regular Sunday meetings.

Typhoid Fever in Eastern Massachusetts.—A series of epidemics of typhoid fever which have occurred recently in Boston, Cambridge, Somerville, and Waltham have been under investigation recently by the Massachusetts State Board of Health. The report states that it is probable that all of these epidemics have arisen as the result of a case of typhoid fever on a milk farm in Sudbury.

Tipping Lawyer Arrested.—A case was brought up before the Tombs court in New York recently of a lawyer who was accused of offering tips to a nurse at Bellevue Hospital for information as to ambulance cases. The nurse swore that the lawyer proposed a rate schedule for ambulance tips. A case involving amputation of a finger or toe was worth $10, that of an arm or leg $15, and death $35. Payment was contingent upon the lawyer obtaining the case.

Pure Food Law Conviction.—A physician recently was found guilty in the United States Circuit Court on an indictment charging violation of the pure food law. The Government contended that the label describing the uncooked wheat bread he sold as a cure-all for stomach trouble was a misrepresentation of the actual properties of the article. The penalty is $250 fine.

Autopsy Suit Dismissed.—The suit for $25,000 damages against a coroner's physician in New York for removing organs from a boy's body and failing to return the same, which was noticed in the MEDICAL RECORD for April 9, 1910, has been dismissed by Supreme Court Justice Bijur. The physician's defence was that he had a right to perform the autopsy because the death was a violent death, and that the spleen was of interest to science because it weighed fourteen pounds. It was sent to a pathological laboratory for microscopical examination.

Antispitting Ordinances.—The National Association for the Study and Prevention of Tuberculosis has issued a bulletin upon the enforcement of the anti-spitting ordinances in various cities. The report states that during the year 1909 in 80 cities, 3,421 arrests were made for violation of the laws regarding spitting in public places. Over 2,900 convictions were secured and $4,100.87 was collected in fines. New York City had more arrests than any other city, having had 2,513, with 2,099 convictions, and $1,936.80 collected in fines.

The Sale of Wood Alcohol.—The New York Department of Health has begun a campaign against sellers of wood alcohol. Inspectors have visited many saloons and liquor stores in various parts of the city and taken samples of liquors offered for sale. Of the first fifteen samples of liquors analyzed three contained wood alcohol. Practically all the liquors containing wood alcohol that have been found up to date were discovered in East Side saloons and liquor stores.

Cold Storage Bill in the Senate.—The Senate Select Committee on the cost of living has made a partial report in the form of a bill introduced by Chairman Lodge. The bill is aimed at the exclusion from inter-State commerce of food held in cold storage for over a year. The bill also requires that any article of food that has been in cold storage for any length of time shall be considered misbranded in the meaning of the Pure Food act unless it carries a label stating correctly the length of time it has been in storage.

To Investigate Cancer in Fish.—President Taft sent a message to Congress last week asking for an appropriation of $50,000 to found a laboratory for the study of malignant disease in fishes. This fact illustrates the pressing need of a national bureau of health to which all matters of this kind could be referred.

Dr. Oskar C. Gruner, Clinical Pathologist to the General Infirmary, Leeds, England, has been appointed Pathologist to the Royal Victoria Hospital, Montreal, and Lecturer in Pathology at McGill University.

Individual Drinking Cups.—The announcement is made that the Pennsylvania Railroad Company

in compliance with the resolution of the State Board of Health, will introduce at all their stations and on their trains paper drinking cups.

Charitable Bequests.—By the will of the late Miss Martha R. Hunt of Somerville, Mass., the following institutions received bequests: Baldwinsville, Mass., Cottage Hospital, $15,000; Home for Incurables, Dorchester, $10,000; Maclean Insane Asylum, $10,000; Perkins Institute for the Blind, $10,000; Willard Hospital, Bedford, Mass., $10,000.

The Hempstead Hospital Association of Hempstead, Long Island, has filed articles of incorporation for the approval of the State Board of Charities. The new association is to take over the South Shore Hospital.

The Babies' Dairy has filed incorporation papers for the approval of the State Board of Charities. The dairy will operate in New York City and is formed to supply proper food to orphans, pauper, destitute, and sick children, and to care for and board such children, and for the education of mothers as to the care and feeding of infants.

The Working Women's Evening Dispensary has been established in Minneapolis. Dr. Mabel Ulrich originated the idea after a study of the conditions of working girls in Minneapolis. A corps of women physicians will be in attendance each night and may be consulted by the working girls in need of services. In all the departments the girls will be given treatment and supplies at cost, but the charges will be large enough so that the dispensary will be self-supporting.

A Clinical Course in Pulmonary Tuberculosis for graduates in medicine will be given at Bellevue Hospital, on Monday, Wednesday, and Friday afternoons from 2 until 4 o'clock, beginning Monday, May 8, 1910. The course will be given by Dr. James Alexander Miller of the College of Physicians and Surgeons, Attending Physician and Director of the Tuberculosis Clinic, Bellevue Hospital, and consists of twelve clinical lectures upon the modern problems of tuberculosis, combined with opportunity for the individual examination and study of a large number of patients. Information concerning the course may be obtained from the registrar of the college, 437 West Fifty-ninth street.

Dr. Massey at the London Cancer Hospital.—During the first week in April, Dr. G. Betton Massey of Philadelphia demonstrated his method of cataphoresis in the treatment of cancer at the London Cancer Hospital.

Rhode Island Medical Society.—The time for the annual meeting of the Rhode Island Medical Society has been changed to Tuesday, May 31, 1910, at Providence, R. I.

The National Association for the Study and Education of Exceptional Children will hold a conference on April 21 and 22, 1910, at New York University, Washington Square, N. Y. The president of the association is Dr. Franz J. A. Torek.

The American Proctologic Society will hold its twelfth annual meeting at St. Louis, Mo., on June 6 and 7, 1910. The headquarters and place of meeting will be at the Planters' Hotel, Fourth and Pine streets. The officers of the association are: *President,* Dwight H. Murray, M.D., of Syracuse, N. Y.; *Vice-President,* T. Chittenden Hill, M.D., of Boston, Mass; *Secretary-Treasurer,* Lewis H. Adler, Jr., M.D., of Philadelphia, Pa.

An International Medical Association to Contribute to the Suppression of War has been formed recently. It will hold its first congress in June, 1911, in Paris. The *President* of the association is Dr. J. Rivière and the *Secretary-General* Dr. J. Mazery.

The Montgomery County (Ark.) Medical Society was organized recently at a meeting at Womble, Ark. The following officers were elected: *President,* Dr. L. S. Kennedy; *Vice-President,* Dr. J. E. Alford; *Secretary,* Dr. J. H. McLean, *Corresponding Secretary,* Dr. J. B. Stuart; *Treasurer,* Dr. I. N. Freeman.

The South Texas Medical Association.—A number of colored physicians of Houston have organized themselves into the "South Texas Medical Association" for the purpose of research and special study of the three most dreaded diseases which afflict their race, tuberculosis, pellagra, and hookworm. The officers of the association are: *President,* Dr. J. D. Daviss; *Secretary-Treasurer,* Dr. E. A. Durham.

The Taylor County (Texas) Medical Society, at a regular meeting held April 5, 1910, elected the following officers: *President,* Dr. F. E. Haynes; *Vice-President,* Dr. C. T. Scott; *Secretary-Treasurer,* Dr. M. M. Carrick of the State Epileptic Colony.

Obituary Notes.—Dr. George M. Bazemore of Cleveland, Tenn., died at his home, March 24, 1910, aged 76 years. He was a graduate of the Bellevue Hospital Medical College in 1874, and was a member of the Bradley County Medical Society, the Tennessee State Medical Association, and the American Medical Association. Dr. Bazemore was the oldest medical practitioner in his county and was for many years chairman of the local board of health.

Dr. Clarence H. Beetle of Berkeley, Cal., died at the Roosevelt Hospital in that city, March 26, 1910, aged 28 years. Dr. Beetle was a graduate of the Cooper Medical College in 1904, and since that time had been resident physician of the Roosevelt Hospital in Berkeley.

Dr. George M. Bell of Benton Harbor, Mich., died in the University Hospital in Chicago, March 28, 1910, aged 62 years. He was a graduate of the University of Michigan in 1870, of the Northwestern Medical College in 1871, and of the Bellevue Hospital Medical College in 1875.

Dr. A. J. Darrah of Enosburg Falls, Vt., died at his home on April 3, 1910, aged 66 years. He was a graduate of the University of Vermont College of Medicine in 1867, and a member of the Franklin County Medical Society, and the Vermont State Medical Society.

Dr. Joseph Simon Girouard of Worcester, Mass., died at the Worcester City Hospital on April 3, 1910, aged 40 years. He was a graduate of Laval University in 1890, and had practised medicine in Woonsocket, R. I., Attleboro, Vt., Manchester, N. H., and Greenville, N. H.

Dr. D. Thomas Long of Topeka, Kan., died at his home, March 20, 1910, aged 63 years. He was a graduate of the Eclectic Medical Institute of Cincinnati in 1882, and was a member of the Kansas State Medical and Surgical Society and the National Eclectic Medical Association.

Dr. J. H. Rice of Pomona, Cal., died at his home recently, aged 83 years. He was a graduate of the Burlington Medical College and practised for many years in Magnolia and Logan, Ia. He retired from

practice twenty years ago and for the past twelve years has lived in California.

Dr. Samuel E. Smith of Nettleton, Ark., died at his home, March 26, 1910, aged 45 years. He was a graduate of the Barnes Medical College in 1904, and was a member of the Craighead County Medical Society and the Arkansas Medical Society.

Dr. Philander B. Taylor of Clio, Mich., died on March 30, 1910, aged 69 years. He was a graduate of the University of Michigan in 1885 and was a member of the Genesee County Medical Society and the Michigan State Medical Society.

Dr. Joseph Warren Odell of Greenland, N. H., died at his home, March 24, aged 79 years. Dr. Odell was a graduate of the Harvard Medical School in 1855, and was a member of the Rockingham County Medical Society and the New Hampshire Medical Society.

Obituary.

ANDREW HEERMANCE SMITH, M.D., LL.D.

NEW YORK.

Dr. Andrew H. Smith, who died on April 8 at his winter home in this city, was for many years one of the most prominent medical figures in New York. He was born in Charlton, N. Y., in 1837, was graduated in arts from Union College in 1853, and in medicine from the College of Physicians and Surgeons of this city in 1858. After graduation he studied at the universities of Göttingen and Berlin, and returning to this country at the beginning of the Civil War, went to the front as assistant surgeon in the Forty-third New York Volunteers. At the close of the war he remained in the regular service as assistant surgeon until 1868, when he resigned and came to New York, where for forty years he led the active life of a practising physician. He was especially interested in laryngology and was for a number of years connected with the throat department of the Manhattan Eye and Ear Hospital, but he never practised that as a specialty, preferring the broader field of general medicine. He was a close observer and clear thinker and the expression of his opinions was always listened to with respect even when his theories were not at once accepted as correct by his hearers. In practice he was full of suggestions and resources, a therapeutic optimist, and therefore a successful practitioner. In his social relations he was genial and pleasant and always welcomed as an entertaining companion. In his professional relations he was most sensitive as to true ethics and upright dealing and was righteously impatient of any deviation from the strait and narrow path of professional rectitude.

Dr. Smith was at different times attending and consulting physician to St. Luke's, St. Mark's, the Presbyterian, the Woman's, and the Post-Graduate Hospitals, and was a member of the New York Academy of Medicine, the Medical Society of the County and that of the State of New York, the Practitioners' Society, American Climatological Association, and Association of American Physicians. In 1903-4 he was president of the Academy of Medicine. In 1907, at the age of 70 years, he retired from the practice of medicine, moving to his summer home in Geneva, N. Y., spending his winters, however, in this city. In that year his Alma Mater, Union College, conferred on him the honorary degree of Doctor of Laws.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

OSLER'S LUMLEIAN LECTURES, ANGINA PECTORIS—CONTRACTED PELVIS, PUBIOTOMY—COLLEGE OF PHYSICIANS PRESIDENCY—OBITUARY.

London, March 25, 1910.

The Lumleian lectures at the Royal College of Physicians have been given this year by Professor Osler, who took for his subject "Angina Pectoris," on which he speaks with the authority of long study and ripe experience. What he had to say was said with his accustomed felicity of expression, making one wish that some other able men were similarly gifted. He defined angina as a disease characterized by paroxysmal attacks of pain, pectoral or extrapectoral, associated with changes in the arterial walls, organic or functional. It is, he declared, primarily an affection of the arterial system—of the pump and the pipes, of the system in which are literally the issues of life and death—and added there is no essential difference in these parts, for the arteries are only a long-drawn-out heart, and the heart but a bulbous expansion of an artery. This physical unit is worked as such and is controlled at every moment by an outside mechanism, an elaborate system of nerves penetrating every part and losing themselves in its structures. After referring to the general etiology, mentioning the interesting fact that angina seems to be specially prevalent among doctors, the lecturer divided his own cases into three groups: (1) Les formes frustes, of the French; (2) mild; (3) severe. The mildest cases form group 1. Its symptoms are substernal tension, uneasiness, and distress, rising gradually to positive pain, a not infrequent complaint from which few people escape. It is associated with three conditions—emotion, muscular effort, and high pressure. These three points differ much in significance. 2. The mild form, "angina minor," of which he had notes of forty-three cases. They comprise the neurotic, vasomotor, and toxic cases, which we used to call false, or pseudoangina, but which the lecturer considers identical with the others. 3. The severe group are those known as angina major, of which he had had 225 cases, 211 of them in men. In all these, or nearly all, there are organic changes in the arteries and liability to sudden death. Though recognizing that it is neither easy nor wise to class cases by symptoms alone, the professor made four groups: (a) Cases of death in the first attack or in a rapidly recurring series—those we have been calling "status anginosus"—and it is in such we meet with the most startlingly sudden death. (b) When a series of twenty, thirty, or forty attacks have occurred in the course of a year or more. (c) Chronic cases, extending over ten years or more.

Prof. Osler next passed to extrapectoral, or, more correctly, extracardiac forms, which may be regarded vascular crises. Of these he gave an exceedingly interesting account. Without asserting they were always due to such crises, he grouped them as (a) peripheral, (b) abdominal, (c) pulmonary, (d) cerebral, according to the prominent features which suggested the several distant vascular disturbances. Most instructive extracardial cases were given as their features appeared to throw light upon the essential nature of the disease.

The Harveian Society has held an important discussion on the treatment in labor of contracted pelvis, particularly in reference to the revival of pubiotomy. It was opened by Dr. F. C. Blacker, obstetric physician to the University College Hospital, in a paper based on a large collection of facts, the value of which was endorsed by subsequent speakers. He grouped the cases according to the degree of contraction. With a conjugate of two and two-fifths inches or less he said abdominal section was always called for. Between that diameter and three inches the ideal treatment was cesarean section, either before the onset or in the early stage of labor. The results were so good as an operation of election that its performance might be extended to a conjugate of three and two-fifths inches, or even more. In unsuitable conditions (version and forceps failing) craniotomy, or embryotomy, must be done. With a diameter of three and three-fifth inches or more spontaneous labor at full term must be waited for. The greatest difference of opinion related to cases with a conjugate between three and three and three-fifths

inches. It is in such pubiotomy had been proposed as a substitute for the induction of premature labor, version, high forceps, or craniotomy. But the maternal mortality of premature labor was in fact practically nil, and the patients recovered better than after full term. The fetal mortality was admittedly high—25 per cent.—but those born alive did as well as full term children. Pubiotomy, in skilled hands, showed 2 per cent. of maternal and 7 per cent. of fetal mortality, the morbidity being 40 and 60 per cent., respectively. It had no advantage over cesarean section for either mother or child, but for the child the mortality was less. There were some patients in whom the comparatively safe operation of cesarean section threatened extra risk, and in whom perhaps pubiotomy might seem less risky if done in proper surroundings, and was preferable to craniotomy on a living child.

Dr. Champneys as a teacher could not recommend pubiotomy to the profession; its general adoption would be a disaster. Cesarean section was in all points better, the risk to mother slight (with no after effects), and to the child nil. If inadmissible craniotomy could be done, which he held had no risk for the mother, those attributed to it being due not to the operation but to the conditions demanding it. He wondered how many patients who could appreciate what was to be done to them had submitted to pubiotomy.

Dr. Herman looked to cesarean section for improvement in the mortality and morbidity of childbirth. It dealt with healthy structures, every step could be foreseen, so different from tumor cases, and there ought to be no mortality. He had not done and did not intend to do pubiotomy—the operator could not control the injuries to the soft parts involved in the separation of the bones after division. It was no use to advise an obstetric operation which admittedly could only be done in hospitals with safety. He added that the age of the fetus was as important as the pelvic measurements.

Dr. W. S. A. Griffith said no exact measurements could be made unless the whole hand was introduced or the pelvis contracted to three inches or less. Other factors were as important. He thought cesarean section required when the head could not enter the brim.

Dr. Herbert Spencer favored induction of premature labor and said the statistics of fetal mortality were not reliable. He had induced labor six times in one woman and five of the children were alive and well, and had had other cases of multiple inductions. Such cases weighed with him more than statistics. Dr. Blacker put the elective point for cesarean section a little too high. He had induced labor at the thirty-fifth week in a three-inch conjugate, the child at birth weighing five pounds and now being a healthy girl of eighteen years. If called when infection or laceration of tissues had occurred, he would prefer cesarean section with excision of the uterus to pubiotomy.

Dr. A. Routh supported the last remark in cases where bruising and possibly infection of tissues had been produced. He instanced such a case where cesarean section had been done and it was hoped infection had not occurred, but within a few days sloughs on the child's head and over the abdominal wound had followed.

Dr. Gow would never do pubiotomy as an operation of choice. He would rather even do craniotomy. He did not think accurate measurements possible even with the hand inside. He could only think of one condition to justify pubiotomy—a case when, after many hours in labor, the head was jammed in the pelvis so as to make cesarean section difficult and dangerous.

Sir Richard Douglas Powell, not desiring to occupy any longer the positon of president of the Royal College of Physicians, Sir Thomas Barlow has been elected his successor. We have, therefore, three ex-presidents living, the other two being Sir Samuel Wilks and Sir William Selby Church.

One of the oldest members of the profession, Dr. Folliott James Sandford, died on the 17th inst., aged 92. He qualified at the College and Hall in 1846-1847 and took the M.D. St. And. in 1862. He had served as Medical Officer of Health at Market Drayton and was consulting surgeon to the hospital there, and had held other appointments. He had also been surgeon-major in a volunteer regiment. He contributed to the old *Medical Gazette* the eighth recorded case of "Dislocation of the Radius Backwards," and to the *Lancet* a case of "Hernia of the Appendix Vermiformis Calci."

The death was announced yesterday of another retired surgeon, John Nettleton Terry, in his seventy-eighth year. He was consulting surgeon to the Bradford Infirmary, M.R.C.S. at S. A. 1855.

Dr. William G. Curgenven died on the 18th, aged 68. He was consultant to the Derby Royal Infirmary and to Trent College, M.R.C.S. 1864, M.D. St. And. 1862. He wrote on "Fractures" in the *Medical Times-Gazette*, 1866.

Dr. J. T. Higgins, surgeon to the South Hospital, died on the 18th inst. L.R.C.S. 1865, M.D., R.U.L. 1868. He was J.P. for the county and held many appointments.

Dr. J. J. Roughton, J.P., surgeon to Hettering Hospital, died on the 19th inst. in his eighty-seventh year. Qualified in 1886. He had been assistant electrician at St. Bartholomew's Hospital.

Brigade Surgeon-Major F. Odevaine, F.R.S.C.I., died on the 20th inst. in his seventy-third year. He served during the Crimean campaign with the Turkish contingent and was awarded the medal.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 31, 1910.

Growing Pains; a Possible Mechanical Explanation.—After a general consideration of this subject, L. T. Brown says that strained or relaxed sacroiliac joints may be a marked factor in causing growing pains in children. The treatment consists in giving support, combined with systematic exercise, to these joints until they are strong enough to carry out their functions without causing any symptoms in the rest of the body. The night pains and morning lameness seen in these children, may be explained as follows: During the day the muscles and ligaments holding the sacrum in place are in a constant state of contraction and the only symptoms are that the child gets more easily tired than other children, and that he cannot run and jump as well as his companions. At night, when sleep relaxes these muscles and ligaments, the sacrum may move or sag, and in so doing strain or irritate the joints and this irritation may be transmitted to the lumbosacral cord or the sacral plexus and cause the child to wake with pains in his legs and back. On waking, the position is changed, the muscles contract, the joints are protected, and the child goes to sleep again, the condition to be repeated with more or less frequency during the night. The ease with which this symptom may be confused with hipjoint disease is evident. In the morning there may be some lameness present when the child gets up, but this soon passes away. The fundamental principle of treatment is to give proper support to the feet. It is usually necessary also to give proper support to the pelvic girdle. This is easily done with a small leather belt which is fastened around the pelvis so that it comes, in front, below the anterior superior spines, and at the back, over the posterior superior spines. The belt is held in place by two perineal straps. This belt is used only temporarily, but if there is much pain it should be worn at night as well as in the day. Exercises should be planned with the idea of strengthening those muscles which tend to correct the faulty posture and not those which tend to exaggerate it.

Correlation of Respiration and Heart Beat During Exercise.—E. A. Wright says that the causes which lead to increased depth and frequency of respiration and to acceleration of the heart rate during exercise are to be considered separately. The two possible paths of connection between the acting muscles and the respiratory center are afforded by the nervous and circulatory systems. Experimental evidence does not support the idea of a pure nervous reflex, but suggests the idea that stimulation is effected through some product of muscular metabolism. The place stimulated is the respiratory center and not the afferent nerve endings in the muscles or the afferent nerves connected with the veins throughout the body. The stimulating agent is CO_2 which is carried by the blood to the lungs, probably in excess of the usual amount. The CO_2 tension (partial pressure) in the alveolar air and so in the arterial blood is thus raised and the respiratory center supplied by this blood is by virtue of its extreme sensitiveness to changes in CO_2 tension aroused to increased activity. In the case of excessive exercise the threshold exciting pressure of the CO_2 in the respiratory center is lowered, due to the presence of lactic acid in the blood. The part played by the vagi in this connection is probably a subordinate one; by regulating the rhythm of the respiratory center they lead to an economy of muscular effort. As regards the heart beat, there is experimental evidence to show (1) that the rate may be accelerated as a result of chemical action and (2) that changes in the chemical composition

of the blood, waste products of muscular metabolism, may act directly on the heart muscle if the work is vigorous and prolonged. The relative importance of the inhibitory and accelerator centers in the medulla, as central stations for a reflex activating the heart, is considered. Inhibition of the cardioinhibitory center at the beginning of exercise, combined with stimulation of the accelerator center later on, is the view favored. The origin of the nervous impulses affecting the cardiac centers is considered. The view that these impulses may be due secondarily to increased respiratory activity is discarded. They probably arise in the acting muscles and cells of the cerebral cortex. The correlation between respiration and the heart beat during exercise is not determined by a common cause, but is determined in part indirectly through the cause leading to increased respiratory activity, but not at the beginning of exercise. It is rather mainly determined by independent causes acting in harmony with each other.

New York Medical Journal, April 2, 1908.

Dissemination of Disease by the Fly.—After some observations on the early work in reference to the house fly as a disseminator of disease and the distribution of the insect, H. G. Beyer passes in review the evidence in our possession as to its influence in transmitting tuberculosis, leprosy, cholera, plague, summer diarrhea of children, carbuncle, frambesia or yaws, oxyuris, tenia, swine plague, and typhoid fever. Special mention is made of the spread of typhoid fever due to flies during the Spanish-American war of 1898. Elaborate evidence is supplied as to the relation of flies to these latter fever outbreaks. The author evidently believes that virulent typhoid bacilli do actually pass through the fly's intestine into the fly specks, about fifty being deposited within twenty-four hours by a single fly. These experiments give us an idea of the tremendous spread of typhoid germs that may be brought about by flies, breeding in infected excrements, when we reflect that one observer was able to hatch out 4,000 flies from only one-sixth of a cubic foot of night soil. These facts would go far toward explaining the hitherto not fully understood perpetuation, year after year, of typhoid occurring in certain localities in the milder climates, especially when we connect their meaning with the calculation made by one observer, viz., that twelve flies hibernating in crevices during a mild winter would send out forty thousand bacillus carriers, flying at the rate of about one mile in five minutes in all directions in search of food on the advent of the warm season.

Methods of Controlling the House Fly and Thus Preventing Disease.—E. P. Felt says that this depends on several factors. 1. The general recognition that flies must find certain favorable conditions for breeding or they cannot become abundant. 2. An understanding of at least the fundamental conditions controlling this multiplication of the insect. 3. A widely spread appreciation that exposed fly producing material is not a necessary accompaniment of our civilization. Some suggestions are given as to matters of daily life. Manure from domestic animals should be stored in fly-proof receptacles. Stables should be kept clean and dry, and should not be located near dwellings. Food kept for domestic animals easily breeds flies. Garbage pails and swill buckets should be kept tightly covered, kept clean, and emptied frequently. Miscellaneous house waste including decayed fruit, sweepings, and dish or slop water should be disposed of so as to prevent accumulation about the premises. Table scraps not used for animals should be burned. All flies should be excluded from the sick room, particularly in cases of contagious disease. Discharges of all kinds must be properly disposed of. All food that is to be eaten without being cooked must be kept from flies. Flies that have not been allowed to gain access to decaying material are comparatively harmless. We shall never be able to eradicate the fly, but can do much to prevent its development. Screening the windows is most commendable. Sticky fly paper is better than the use of poisonous preparations for dead flies may fall into the food. We should do away with pools of stagnant water. The warfare carried on against the mosquito shows what may be done in this direction.

Milk Intoxications by Ergotic Flora.—C. B. Fitzpatrick has made certain observations with regard to the infection of milk by ergotic flora, and reaches the following conclusions. (1) These investigations furnish a suggestion for the experimental investigation of milk intoxications. It is self evident that if these toxic agents can obtain entrance into the milk and cause disease, the substances which contain them, such as various members of the numerous plant disease fungi and similar organisms holding toxic bodies, can do likewise if they gain access via the fodder. The whole subject of the absorption of toxic agents in cows and their milk elimination thus demands investigation, prevention, and treatment. (2) A list of the toxic or poisonous weeds which occur in the fodder of cows in the New York city milk zone and elsewhere also becomes of significance. Likewise the activities of the agents which cause plant diseases of cow fodder. (3) The lesions of the digestive tract of the cow are also of vital importance, because we know that in these digestive diseases the toxic agents are not rendered harmless or neutralized, but eliminated directly as such. (4) That given an exact physiointoxication assay of the toxic agents of weeds, fungi, etc., in cow fodder, it would be practical to construct a table of say the fifteen or so of the most important of these poisons by their diagnostic reactions, for the qualitative analysis of milk intoxications, and thus perhaps recognize the poison and prescribe the appropriate therapeutic measures. (5) That the use of ergot as medicine should be much restricted. (6) The tests, as reported in literature, "of ergot have revealed a condition of affairs that may justly be said to be horrifying." A sample of ergot may be used for its stimulant or contractile effects, for instance, and have no such effects, but the opposite effects, and even the toxic and gangrenous results of ergot poisoning may result. Hence, the urgent necessity of comprehensive and exact assay of these agents such as outlined under conclusion 4.

Journal of the American Medical Association, April 2, 1910.

Modern Antiseptic Surgery.—W. W. Keen gives a history of the development of modern antiseptic surgery and of the rôle of experiments in its discovery and growth. He describes the conditions in the preantiseptic period when pus was always "on tap" and considered unavoidable, when surgical fevers were the rule, and secondary hemorrhages were also frequent, lock jaw and gangrene were common, and compound fractures and open joints were in more than half the cases fatal. The details and discovery of the antiseptic method by the researches of Pasteur, Lister, and their followers, together with the discovery of the infectious germs of surgical disease, are given in detail. Practically the progressive introduction of the antiseptic method from compound fractures up to deliberate surgical operations was, Keen says, one vast experiment in the human living body—an experiment justified, as all the world well knows, by its splendid and continuing results. Yet when in 1880 or 1881 Lister wished to make additional experiments on animals to perfect his method still further, so stringent was the law in Great Britain that he was obliged to go to the Veterinary School at Toulouse, France. What the results have been is shown by Keen. Most wounds now heal within a few days, one might almost say without the patient being ill, compound fractures and open joints heal as if there had been no break in the skin. Arteries can be tied anywhere without fear of secondary hemorrhage. The abdomen is now fearlessly opened. When Keen was assistant to Dr. Washington Atlee in the late sixties, two out of three of his ovariotomy patients died, yet he was then the most famous operator in America. Now any surgeon who loses more than five out of one hundred is looked at askance by his colleagues, and many hundreds of patients are operated on with a mortality under 1 per cent. The abdominal cavity is almost the surgeon's playground, and it does not contain an organ that has not been subject to operation. In obstetrics the same happy results have been obtained; puerperal fever, which used to kill frequently one-half or two-thirds or more of the women in a maternity hospital, is now almost unknown, and the preantiseptic general mortality in maternity cases has been reduced from 10 per cent. or more to 1 per cent. or less. Compound fractures now have a mortality of 1 or 2 per cent. or less, instead of over 60 per cent., and very rarely require amputation. The most striking evidence of the value of antiseptic treatment, however, was seen in the results of hospital treatment, and three notable instances occurring shortly after its introduction are quoted, the most extraordinary of which was that obtained by Lister in his own hospital in Glasgow. We are still, however, far from perfection. There are many problems of disease, still waiting solution, which can be solved by the experimental method. A number of organs are as yet inaccessible and there are others of

which we have yet to learn the functions. The causes of many diseases are yet unknown, and to dispel this ignorance and to discover a cure is the work of experimental medicine. Shall this be favored by the community? or shall we, by restrictive legislation, call a halt and give disease and death their free course? The answer, Keen says, is clear. It will never be other than an emphatic no to the latter.

Duties of Medical Officers.—L. B. Ashton, after noting the history of modern military surgery and pointing out some of the mistakes that have been made, advocates the endowment of chairs of military surgery and sanitation in the principal medical colleges of the country and the assignment of this branch of medicine to some correlated section in the State and national medical organizations. Ashton points out some of the duties of the military surgeon and especially as they are required in the tropical dependencies of the country at the present time, where, in the conquest of tropical diseases, American military surgeons have already earned a distinguished name. He regrets that more militia surgeons have not availed themselves of the advantages given by the throwing open of the Army Medical School at Washington, admitting them to its privileges with the regular army officers.

The Army Medical Service.—The lack of definite knowledge on the part of the general practitioner of the privileges and opportunities of the army surgeon is noted by Eben C. Hill, who quotes from an address to a graduating class of the army medical school in 1894, by Dr. Osler, in support of his contention. He emphasizes the fact that an army post contains, besides soldiers, who are not generally supposed to have a wide range of diseases, also women and children who come under the care of the post surgeon. Contrary to the rather general impression, venereal cases play a subordinate part in the sum total of disease at a post. While soldiers are not usually invalids, being selected men, they are subject to the ordinary infections and troubles, and the practice of the army medical man covers, as he shows by a statement of the classes of cases actually treated in three months at one post, a very wide range of disorders. The hospitals are thoroughly equipped for all kinds of surgical work and with necessary medical supplies, and the laboratories contain all facilities for clinical study. The leading American and foreign journals are taken and a rather complete library furnished. It is possible that a surgeon may be alone at a post, but this is exceptional, and the opportunities altogether are especially good for advancement in professional knowledge.

Proctoclysis.—An apparatus for continuous proctoclysis is described by Angus McLean. It consists of a galvanized iron or tin box, size 7 by 8 by 9 inches, the walls, floor, and cover of which are made of two layers with asbestos between. For the front two layers of glass instead of metal are used. A two-quart dish for the saline solution is placed in this box. The solution falls drop by drop into a funnel and is carried by a double-walled tube into the patient's rectum, a strip of gauze carrying it over the edge of the dish into the funnel, a strip giving fifty drops a minute being used. The water is kept at a definite heat of from 140 to 145 F. by means of an electric bulb or alcohol lamp under the dish. If any obstruction occurs it can be observed by the fluid filling the funnel. There can be no constriction of the tube by the arrangement used and obstruction would have to be caused by feces or pressure of the thighs, or in some other way. The apparatus furnishes a perfect drop which can be regulated to suit the needs. It allows for rapid expulsion of flatus, is inexpensive, and can also be improvised in any household with a basin, a funnel, a tube, and piece of gauze.

Epidermidolysis Bullosa Congenita.—J. R. Kanoky and R. L. Sutton report a case of this disorder, of which there are only about a hundred reported in the literature. A microscopic examination was made of the uninjured integument of the child, away from the lesions, showing the absence of the elastic fibers between the two major layers of the skin. They agree with Pusey in considering that these elastic fibers constitute an important factor in binding together these layers and their absence in epidermidolysis bullosa, or rather in the skin of the subjects of this disease, is the cause of its development after slight injuries. As the condition is undoubtedly congenital and hereditary in only about half the cases, the term "congenita" substituted for "hereditaria" seems to him more appropriate.

The Lancet, March 26, 1910.

The Abdominal Watersheds and Their Influence on the Localization of Intraperitoneal Infections.—C. R. Box divides the peritoneal cavity into various watersheds or drainage regions and discusses the tendency of lesions in the cavity to drain in accord with the directions of these regions. When a purulent infection begins to descend the declivity which slopes from the pelvic ridge toward the right loin it naturally tends to travel along the ascending colon which lies on this slope. The colon being usually more or less distended divides the slope into two gutters to which the names external and internal paracolic grooves have been applied. The external which lies between the colon and lateral abdominal wall leads directly to a well around the head of the right kidney. To this well also the mesocolic slope tends to direct effusions poured out in the upper part of the abdomen. Thus the right renal well or subhepatic pouch is of importance not only in connection with lesions in the upper part of the abdomen but also with the more common lesions of the appendix. Ascending infections may not only affect the right renal well but tend to make their way between the left lobe of the liver and the lateral wall of the abdomen into the right subphrenic space. Following along this general line of description the author then considers the anatomical boundaries of the recesses in which pus finally tends to accumulate and the signs which are diagnostic of its presence at these spots. Above the mesocolic shelf (transverse colon in connection with the great omentum) there are three situations in which suppuration may occur. First, the pus may lie in the right dome of the diaphragm constituting the true right subphrenic abscess. Second, it may lie in the left dome occupying part or all of the space known as the stomach chamber; this is the left subphrenic abscess sometimes called perigastric or perisplenic from the relations it bears to the stomach and spleen. Third, pus may lie below the right lobe of the liver in the recess known as the right renal well, right kidney pouch, or subhepatic fossa. When the purulent collection is very extensive its distribution may be widespread so that all the cavities are simultaneously involved. The author then gives the clinical histories of four cases which illustrate the anatomical points made by him. The treatment of all these forms of abscess is essentially surgical. Drainage is called for. Localization takes from seven to ten days or more. Dangers of secondary diffuse peritoneal infection, infection of the pleural sac and lung, and of portal pyemia are always present. The findings of the aspirating needle are often fallacious. It should never be used for puncture below the ribs nor below the diaphragm on the left side. In doubtful cases exploratory incision is the safest course in the long run. Extensive right subphrenic abscess caused by recent rupture of a gastric or duodenal ulcer is usually first explored from the front and if the pus collection is found localized, posterior transpleural drainage is usually adopted. If due to appendicitis it may be treated by an incision high up and far back in the flank but if the collection is of any magnitude it is better to open the subphrenic space higher up by the transpleural route, steps being taken to shut off the pleural cavity. The author advocates the Fowler position as the one in which appendicitis cases should be nursed. This position has the merit of preventing ascending infection but it favors drainage into the pelvic cavity and this fact should not be lost sight of.

The Treatment of Psoriasis.—E. G. Graham Little offers certain observations on the diagnosis of this condition and dwells on the character of the initial lesion. Of all local applications he prefers chrysarobin which may be applied in various ways as it is soluble in ether, chloroform, and benzine. It must be kept from the conjunctiva and if used on hairy parts must be carefully washed off before soap is applied, otherwise there ensues a purple discoloration of the hair. For small patches it may be applied in sticks made with white wax and lanolin. For exposed parts an ointment of 15 grains to the ounce is strong enough. In psoriasis of the scalp after removal of the scales an ointment of sulphur, camphor, liq picis carb., carbolic acid, and resorcin may be used; also an ointment containing oil of cade which is less difficult and cheaper to make. Oil of cade is probably the remedy next best to chrysarobin if the latter cannot be tolerated, but this rarely happens if one is careful. Tar baths may also be used and *x*-rays and light rays. In cases of acute and extensive disease chrysarobin may be applied to the whole body, the patient being kept in bed, the point aimed at being desquamation of the whole body under the remedy

and this treatment is kept up until the result desired is attained. Internally, arsenic has been much used and in children and in first attacks it is of service but is not as specific as mercury is in syphilis and its use does not prevent the appearance and spread of an eruption and the danger of forming an arsenic habit must be remembered. The use of that form of arsenic known as atoxyl is dangerous. Salicin has been used with very irregular results. Copaiba resin and potassium iodide have also been given. Many of these patients are neurotic and must be treated accordingly. The author is not an advocate of any special diet. The eruption can nearly always be dispersed even if the patient is not fully cured.

On a Case of Heart Block.—J. G. Emanuel describes the case of a small man of fifty-six years of age, who had a severe rheumatic attack at the twentieth year. All through his life thereafter he had attacks of momentary unconsciousness. When seen by the author the heart was found to be rather small, the pulse strong and full, and while a systolic murmur was audible at the apex that in itself was not considered sufficient to account for the frequent syncopal attacks and the persistent dyspnea on any but the slightest exertion. The most prominent symptom was the bradycardia and a diagnosis was made of heart block of Stokes-Adams disease. The author discusses the nature of this disease and refers to recent experiments by Erlanger on the mammalian heart. The bundle of muscular fibers involved in such cases has the form of an inverted Y which commences in the auriculoventricular node situated in the wall of the interauricular septum near the opening of the coronary sinus into the right auricle and passes down in the interauricular septum through the fibrous auriculoventricular ring into the interventricular septum where it divides at the lowest part of the pars membrane septi into two branches, one passing into the wall of the right and the other into the wall of the left ventricle. Finally the fibers of each branch spread out under the entire endocardial lining of the ventricular cavities. Erlanger found that by very slight compression of this bundle the interval between the contraction of the auricle and that of the ventricle was increased. With further compression a ventricular beat was regularly missed. In the present case the pulse beat ran from 36 to 42 per minute. Blood pressure was high. There was no cyanosis or edema of the extremities. Urine was free from albumin and sugar and there was no enlargement of liver or spleen. Pupils were normal. Knee-jerks were exaggerated. Pulse tracings are given. No satisfactory treatment has been found for this class of cases. In the syncopal and convulsive attacks rapidly diffusible stimulants and the nitrites may be of service. Many of the cases have shown, on autopsy, gummata, and potassium iodide might be given. Such drugs as strophanthus and digitalis are injurious. For this group of drugs diminishes conductivity along the auriculoventricular band and if pushed to excess will produce the condition of heart block. It is evident then for this if for no other reason the recognition of these cases is important and in every case in which there is persistent bradycardia, simultaneous tracings of the jugular and radial pulses ought to be taken, this being the readiest means by which this condition may be diagnosed with certainty.

British Medical Journal, March 19 and 26, 1910.

The Local Injection of Sodium Salicylate in Acute Rheumatism.—B. N. Ghosh says that in whatever form salicylic acid is taken it is converted into sodium salicylate in the blood and that the carbonic and phosphoric acids of the blood are constantly striving for the possession of the sodium. The salicylate has analgesic, antithermic, chologogic, and eliminative properties. Moreover, the bacterium of rheumatism, whatever it may be, is acted upon by the remedy with the same certainty as with mercury in spyhilis and quinine in malaria. This action is a local one, and the author decided to treat his rheumatic cases by injection of the salicylate. This has been done by Santini. He gives no explanation, but observes that the tendency to relapses was greater. Others recommend the deep injection of 1 per cent. solutions of carbolic acid. Still others have used a 10 per cent. solution with great relief to the joint pains. It appears to Ghosh that the curative effects of these methods lie not in the carbolic acid but in its conversion into salicylic acid, which in the laboratory is prepared by the action of CO_2 upon carbolates. We know that the carbolic acid is transformed into a carbolate in the blood and tissues. Therefore, when the carbolic acid is injected into an inflamed joint the carbolate comes in contact with the nascent CO_2 the result of the local inflammation with the effect that the free salicylic acid is formed which asserts its influence there. The author makes no mention of his own clinical results.

A Case of Family Albuminuria.—J. N. Ferguson refers to a family, all of whom were passing albumin. They were all of middle life and over and all appeared perfectly well. He calls attention of the significance of this fact to the matter of eligibility for life insurance. In one special instance alluded to, the condition had been present for at least twenty-five years. No casts were found and there was nothing in the patient's symptoms or condition to indicate kidney trouble. In fact, the existence of albuminuria came to light only incidentally. The heart was normal in size, the sounds were normal, the blood pressure was within normal limits, and there was little or no arterial thickening. At no time had there been any edema of the eyelids or legs. The albumin was serum-albumin and was present to the extent of 3 grams per liter. It is difficult to explain such cases. There is usually some relation between the passing of the albumin and excessive physical exertion, excessive ingestion of albuminous food, or emotional causes. One of the functions of the kidney is to prevent the escape of the albuminous matters from the circulation and the explanation of most cases of albuminuria is that one kind of disease or other either by directly damaging the organ or by indirectly interfering with its nutrition has impaired this function in greater or less degree. A few persons may have kidneys in which the albumin function is only imperfectly developed.

Acute Tuberculous Bronchopneumonia After Gastroenterostomy.—The patient whose history is herein described was under the care of W. A. Mackay, I. Macdonald, and H. A. Sutherland. These authors comment on the pulmonary complication to be feared after major operations of this nature but by careful disinfection of the mouth for some days before operation, by avoidance of chill during the preparation of the patient, by the minimum exposure of the viscera, and by the adoption of the elevated position whenever the effects of the anesthetic have passed off, much can be done to lessen the postoperative danger to the patient. The operators named above have lost one man out of 80 cases from pneumonia and two patients from cancer, death being due to "vicious circle." The present case was that of a man aged 39 who gave a long history of severe epigastric pain without vomiting, usually most severe in the early hours of the morning. After five days of hospital observation, the abdomen was opened above and to the right of the umbilicus, the right rectus muscle being pulled aside. About one inch beyond the pyloric venous plexus on the upper surface of the duodenum an irregularly rounded ulcer the size of a sixpence with a hard indurated base was found. Posterior gastroenterostomy was performed and the patient returned to bed in good condition. He did well till the sixth day when there was an onset of what proved to be tuberculous bronchopneumonia. It ran the usual acute course for two weeks. Prior to the operation the patient had neither cough, sputa, nor abnormal chest signs. It is probable, however, that he had a latent focus of infection which required only a lowered resistance to break out into this grave form of phthisis. Any suspicion of the duodenal ulcer being tuberculous was negatived by the clinical history, the appearance of the ulcer at examination, and a negative result in examining the feces for tubercle bacilli. The patient died in six months from this form of acute tuberculosis. The incidence of phthisis supervening on chronic gastric or duodenal ulcer varies from 20 to 27 per cent. and, in view of the fact experimentally proved that a lesion of the intestine favors the absorption of tubercle bacilli into the lymphatic and circulatory systems, by either of which routes they may reach the lungs, there is a clear indication for the earlier resort to surgical measures in cases of chronic ulcers which are not benefited by medical treatment. On the Continent it has been generally believed that the danger of the operation of gastroenterostomy itself is practically nothing compared to the risk of postoperative pulmonary infection which usually takes the form of bronchopneumonia.

Death Under Spinal Anesthesia by Jonnesco's Method in a Case of Acute Intestinal Obstruction.—Encouraged by his success in one case of intestinal obstruction operated on by this method of anesthesia, F. V. Milward tried it on a second patient, a man of fifty years admitted to hospital with symptoms of intestinal obstruction which had lasted eight days. He was much distended and vomited fecal matter very frequently. This in the surgeon's mind rendered general anesthesia out of the question and an injection of 10 cg. of stovaine and 1 mg. of strychnine in 1 c.cm. of water was made in the dorsi-lumbar region. On account of the patient's condition and abdom-

inal distension it was impossible to employ the sitting posture and forward arching of the back to any advantage and it was only after three attempts that the insertion of the needle was accomplished. In seven minutes after injection the patient's pupils began to dilate and his pulse to fail. In a few minutes he became unconscious, vomited profusely, and his respiration became very shallow. Fifteen minutes after injection his pulse was imperceptible and he was practically dead. Various measures of relief were tried without effect. Autopsy showed both visceral and parietal layers of the peritoneum studded with small nodules of gray malignant growth, thickest in the pelvic region and at the mesenteric attachments of the gut. The sigmoid flexure was severely kinked by the attachment of a nodule of growth in the omentum to an epiploic appendix; a little free fluid was present. The appearance of the spinal cord was perfectly normal. No hemorrhage was noted inside the spinal theca and the technical part of the injection appeared to have been properly carried out. There can be no doubt that the man's death was due directly to the toxic effects of the stovaine and strychnine given by injection. Shock caused by traumatism was negatived by the absence of any definite injury to the cord or its membranes but the sudden and fatal onset of cardiac and respiratory failure was exactly what might be expected of a reagent producing the same changes in the medullary region as was purposed to be produced in the lower dorsal segments of the cord. The author has previously operated on a similar patient without any disturbance. In this case the complete analgesia of the entire abdomen, its complete relaxation together with the entire absence of peristalsis and inclination of the distended bowels to press through the wound were most satisfactory experiences in abdominal surgery and he was inclined to think that the ideal method of anesthesia had been found. He believes that it would have been dangerous in the patient here mentioned to have given even a less concentrated dose of stovaine. Jonnesco utters no grave warning against full doses but does advise that the amount of 10 cg. shall be reduced in cases of severe illness and has extolled the wonderful safety to be acquired by the combination with strychnine.

Optic Neuritis and Suppurative Otitis.—J. S. Barr and J. Rowan have made a further investigation into the frequency and significance of optic neuritis and other vascular changes in the retinæ of patients suffering from purulent disease of the middle ear. Their results are presented in tabular form and must be studied by those interested. The following conclusions are presented (1) Optic neuritis may occur in cases of purulent middle ear disease without obvious signs of an intracranial complication, 11 times in 160 cases of 6.8 per cent. (2) Apart from optic neuritis vascular changes of a lesser degree are frequent, 39 times in 160 cases or about 25 per cent. (3) Cases of purulent middle ear disease in which the optic neuritis or vascular engorgement of the fundus is present are much less amenable than those in which the fundus is normal. (4) As a general rule an improvement in the eye condition is accompanied by an improvement in the aural condition while an increase in the intensity of the changes in the fundus or their persistence is associated with less amenability to treatment and greater gravity of the ear condition. (5) The most probable cause of vascular engorgement of the fundus or optic neuritis is serous meningitis, localized or diffused. (6) Optic neuritis caused in this way is not usually followed by atrophy and unless there are other symptoms demanding it, opening of the dura is unnecessary. The practical lessons deducible from the foregoing are that a case showing these changes in the fundus should be closely watched, and their existence regarded as an additional reason for the early performance of the radical mastoid operation, and if on the other hand they show a tendency to clear off, especially with improvement in the ear condition, or if the fundus is normal to begin with and remains so, we may with more confidence look for a favorable response to conservative treatment.

Berliner klinische Wochenschrift, March 7 and 14, 1910.

The Treatment of Perforated Gastric Ulcer.—M. Martens says there is no condition demanding a rapid diagnosis more than perforation of a gastric ulcer. The cases are often confused with appendicitis and allowed to die owing to conservative treatment. The diagnosis in the early stages should not be difficult. Most of the cases have complained previously of stomach trouble. Though there may have been no hematemesis or intestinal hemorrhage, there is usually a history of pain directly after meals. The characteristic symptoms are the sudden lightning-like pain and collapse. The temperature may be raised or subnormal. In some cases the pulse is very rapid, in others it is slowed. The leucocytes are as a rule high. Vomiting occurs in one-third of the cases. The tongue becomes dry very early. The whole abdomen is spontaneously painful. The chief pain is in the epigastrium or near the navel; it may be over McBurney's point. The abdomen is board-like. On admission to the hospital the author has the patient put to bed, the extremities wound in flannel, and hot water bottles applied. He is then given morphine, scopolamine, and caffein. Then immediate operation is indicated, preceded by an infusion if necessary. The best antidote to shock is closing the perforation. The two purposes of operation are the closing of the perforation and the toilet of the peritoneum. He advises against excising the perforation. He stitches it up in two stages. The stitches should be taken parallel to the long axis of the stomach, especially near the pylorus. If the ulcer has produced a stenosis, a posterior gastroenterostomy is indicated. The second stage of the operation is the peritoneal toilet. He prefers irrigation to washing. He uses physiological salt solution of a temperature from 99° to 104°. He usually makes a secondary incision in the ileocecal region, through which the pelvis is irrigated and drained. Of the last eighteen cases so treated by the author, eight have recovered.

Two Rare Cases of Retention of Urine.—L. Casper reports two peculiar cases. The first, a man of 68, free from nervous or other diseases, and with a normal prostate, had had complete retention of urine for eight years, necessitating a catheter life. This is probably a case of "age bladder," due to fibrous degeneration of the muscles of the bladder wall. The second case was of a man of 34 years of age, who had had complete retention for six years. This patient also showed signs of atrophic condition in the skin. Casper believes that in this man also there is atrophy of the bladder muscle. In both cases Casper inserted permanent catheters.

The Casein Content of Woman's Milk.—Engel and Frehn have analyzed a considerable number of specimens of woman's milk in respect to the casein content. The specimens varied from the eleventh to the two hundred and twenty-third day of lactation. Their conclusions are that the casein nitrogen makes up from 40 to 45 per cent. of the total nitrogen. The casein content of the milk varies from 0.4 to 0.6 per cent. The relative amount of casein in the milk varies greatly in the same person, for which no laws can be laid down. The various factors which influence the composition of woman's milk, as period of lactation, individuality, phase of nursing, and intermission between nursings appear to play no especial rôle in the determination of the casein content.

The Diagnosis of Cancer of the Rectum.—L. Kuttner describes the case of a man of 51 years who came to him for indigestion, slight irregularity of the stools, and loss of weight. An examination of the abdomen and the gastric functions showed nothing abnormal, but as a little blood was found in the stools a rectal examination was made and a small ulcer seen, 11 cm. from the sphincter. A piece was excised and the diagnosis of adenocarcinoma made. The rectum was excised. The ulcer measured only 1.5 x 2 cm. The author emphasizes the necessity of making a rectal examination in every case suggesting cancer, and the importance, if an ulcer is seen, of excising a bit for examination.

Münchener medizinische Wochenschrift, March 8 and 15, 1910.

On Muscle Hernia.—Lexer and Baws say that the term muscle hernia is applied to a clinical picture, most commonly seen in connection with the biceps muscle after a trauma, a sudden strain, or disease of the fascia. There appears a soft pseudofluctuating tumor which becomes hard with muscular contraction. Usually when the muscle is relaxed the slit in the fascia can be felt. The pain is slight. Cases also occur in which the fascia is not torn, but only thinned so that the muscles bulge it out. In others, the muscle has been torn and the tumor which one feels is in reality the loose end of the muscle. The condition may be simulated by tearing loose of one head of the biceps. The authors have carried out some animal experiments, from which they conclude that a pure muscle hernia without associated rupture of muscle can be considered to exist, only when a muscle tumor protrudes during relaxation through a palpable tear in the fascia, and disappears on muscle contraction. If the muscle tumor increases during contrac-

tion, one is dealing with a ruptured muscle. If the slit is palpable in the latter condition the lesion is a combination of injury to the fascia and tear of the muscle. In the absence of a palpable slit in the fascia, a muscle tumor increasing during contraction is an uncomplicated tear of the muscle.

The Action of Sublimate Upon the Wassermann Reaction.—Satta and Donati refer to a former paper in which they suggested that the Wassermann reaction was the result of ferment activity. In a search for substances which would paralyze the Wassermann reaction they hit upon sublimate solution. They found that the addition of a trace of bichloride absolutely prevented the action of the Wassermann reaction in syphilitic sera. The Wassermann reaction, however, reappeared if to the bichloride solution was added some substance which would dissociate the mercury salt, as potassium cyanide.

Deutsche medizinische Wochenschrift, March 3 and 10, 1910.

A Case of Diabetes Remaining Cured for Ten Years.—Teschemacher refers to the scant literature on cured and latent cases of diabetes mellitus and then reports a case of his own, a man of 57 years of age, who first came to him in the summer of 1899. The patient was an exceptionally large, powerful man, who, in recent years, had not done any work, owing to the shock of an injury in which his testes were crushed. Some years after this accident the patient became ill with weakness and emanciation and a mild grade of diabetes mellitus. He came under the author's care a few months later. Physical examination showed nothing abnormal. The urine contained 2.7 per cent. of sugar, but no albumin or acetone. After four weeks on a strict diet the urine was sugar-free. At the end of five weeks the patient was discharged, taking daily 150 grams of bread and some potato and fruit without glocosuria. The author did not see the patient again for ten years. During that time he had returned to a full mixed diet, and systematic urine examinations made every few weeks had failed to demonstrate any sign of the previous diabetic condition. At the second visit the patient was suffering from chronic nephritis. The author then refers to a series of cases seen by him in 1902, in which two children, one four years old and the other fourteen months old, suffered from what appeared to be acute diabetes, but recovered. At the same time their parents both had glycosuria, the mother's transient, the father's continued. The author states that all these cases took his "cure," but fails to mention of what that consists.

The Clinical Picture of Tooth Retention.—A. Ffister says that our knowledge of the diseases caused by the retention of teeth has grown rapidly during the last few years, this being in no small degree due to the use of the *x*-rays. The cause of the retention may be that the original deposition of the tooth germ was in such a deep position in the jaw that the developing tooth was unable to penetrate the overlying bone; it may be due to the seed having been placed at an improper angle so that the line of growth is not towards the usual point of eruption, and the tooth grows out towards the gum behind the jaw, into the lip, into the nose, or into the anthrum. A second cause is too small a jaw bone crowding the tooth out of its natural position. The third cause is inflammatory or traumatic changes in the jaw. The symptoms of the condition are varied. There is usually more or less swelling of the alveolar process over the point where the tooth lies buried. Next to the swelling the most common symptom is pain, which may vary from mild discomfort to intense agony. The pain is usually of a neuralgic character. The reason for it is not always clear. It may be a true neuralgia from the root or the crown pressing upon a nerve. This is most commonly the case with the molars of the lower jaw, which when misplaced may press upon the nervus mandibularis. Rarely the roots of the teeth grow together, and in so doing surround a nerve or the entire mandibular canal. If the pain is slight and the axis correct, the tooth should be allowed to take its course. In other cases of removal of bone the tooth may be straightened. A complication which may call for surgical interference is an inflammation of the jaw. This may be of one of three forms, an ulcerative stomatitis or pressure ulcer, a periostitis, or an inflamed alveolar cyst. In long standing inflammation there may be fistula formation, and granulations suggesting neoplasm. The surgical importance of such cysts and tumors is that radical operations should be avoided. The symtoms of tooth retention usually appear between the fifteenth and thirtieth year, though they have been seen as early as twelve, and as late as seventy. The canine tooth is the most frequently involved, then the incisors and the wisdom teeth. The *x*-ray makes the definite diagnosis very simple. Three cases are reported.

Treatment of Myomata by the X-Ray.—Schindler reports twelve cases of myomata treated by the *x*-ray. In no case did the treatment cause increased bleeding. The author considers that in the *x*-ray we have a most valuable means of treating myomata, far superior to all other known methods except operation, and that frequently *x*-ray treatment spares the patient the hardships and dangers of operation.

Tuberculous Meningitis in the Aged.—J. Jaquet says that while tuberculous meningitis is primarily a disease of youth, it may also occur in the aged. Of 621 cases of tuberculosis treated in his hospital, to which only adults were admitted, there were 16 cases of tuberculous meningitis confirmed by autopsy. Nine of these were between the ages of 17 and 40 and seven above 40. These last seven he reports and analyzes. Four were men and three were women. The clinical picture was quite uniform, but varied markedly from that of the disease in childhood. The most common symptoms were stupor and coma. Delirium was not frequent. Vomiting was absent in most of the cases. Spontaneous complaint of headache occurred in but two cases. Retraction of the abdomen occurred but once, and retraction of the head was very rare, as was also Kernig's sign. The pateller reflex was absent but once. Babinski's reflex was positive once. The fever was variable; once it was absent, once very slight. Eye symptoms were slight, in only one case there being strabismus. In three cases there was retention of urine; in one, incontinence. The course of the disease varied from 5 to 20 days.

Hysterical and Spastic Intestinal Obstruction.—O. Nordmann says that intestinal obstruction may be caused by a spasm of the musculature of a section of the gut. The cause of the cramp lies in a general nervous condition, especially in hysteria. There are cases in which the most careful examination of the patient is fruitless, and the section either at operation or postmortem fails to throw any light upon the cause of the conditions. It is important in every case where there is a suspicion of an obstruction due to muscular spasm that the patient at once be removed to a hospital. The therapy, if the nervous foundation of the condition is evident, may be conservative, so long as the patient's general condition remains good. If the condition grows worse an enterostomy is indicated to empty the distended loop and prevent autointoxication. The prognosis of the attack, provided the gut is not paralyzed, is good, especially when the cause of the spasm is nervous. It is bad when the paralysis, which is often associated with the spasm, cannot be overcome.

A Contribution to the Functional Diagnosis of the Kidney.—Julius Vogel discusses the proper procedure in cases of kidney disease in which urethral catheterization is not possible. One must make as much use as possible of the classical methods of examination, palpation, percussion, and chemical and bacterial uranalysis. Next in importance comes cystoscopy, if it can possibly be done. With simultaneous injections of indigo carmine rather extensive information as to the functional activity of the kidneys may be obtained by cystoscopy, even without ureteral catheterization. Next the phloridzin test should be made and cryoscopy of both blood and urine done. If the latter gives repeatedly bad results, the author advises against the operation. If cryoscopy is out of the question, the following procedure, recommended by Casper, may be carried out. Before the operation a catheter is inserted into the bladder. Then, after dissecting out the ureter of the kidney to be operated upon, this is clamped off and at the same time injections of indigo carmine and phloridzin are made. By this means one can learn quickly the condition and functional activity of the opposite kidney. This method is, of course, open to greater errors than ureteral catheterism, but it is used only as a last resort. He especially recommends cryoscopy of the blood and urine in all cases, and emphasizes its significance as an indication for operation.

Two Cases of Alopecia with Arrest of Development Localized on the Cranial Vault.—Lequeux describes a peculiar failure of development of the cranial vault and the skin covering it, which results in a localized baldness, and a deficiency of the bone of the vault. He notes two cases of this malformation. It occurs in all degrees from a small spot of baldness and a small absence of bone tissue, to a large defect covered only within a thin layer of fibrous connective tissue. The defect is always between the two fontanelles.—*Bulletin de la Société d'Obstetrique de Paris.*

Book Reviews.

Surgical Anæsthesia. By H. Bellamy Gardner, M.R.C.S., L.R.C.P., London; formerly Anæsthetist and Instructor in Anæsthetics at Charing Cross Hospital; Anæsthetist at St Mark's Hospital for Fistula, the National Orthopædic Hospital, and the Male Lock Hospital; Assistant Anæsthetist at the Royal Dental Hospital of London. New York: William Wood and Company, 1909.

The keynote of success in anesthesia is that the patient should receive the anesthetist's undivided attention; that each patient should be considered as an individual who shall receive his narcotic according to his peculiar needs and susceptibility, not as a body through which so many grams of gas is to be passed in so many minutes. This is the note most happily struck in the present volume. The first part of the book is taken up with the patient, the signs of anesthesia, the physical type and temperament, and the pathological condition of the subject. The cardinal principles of anesthesia are given to "maintain a clear airway" and "to make absolutely sure of the exact degree of narcosis present." The beginner is told "that he must either feel or hear every respiration." Types of breathing—rapid, deep, shallow, and irregular—each receives its paragraph. The second half of the book takes up the various anesthetics—nitrous oxide, ether, chloroform, and ethyl chloride. Under these headings the methods of administration are given, and the more common forms of apparatus described, but here, too, one gets the impression that observation of the patient is the all-important point. The last few chapters briefly discuss anesthesia in its relation to regional surgery, surgical shock, emergencies, and after-treatment. For a book of its small size the present work is exceptionally complete. It is written to tell the student what he should know as briefly as possible, a purpose which is accomplished without sacrifice of literary style or loss of clarity. It can well be recommended to every senior student and hospital interne.

Diseases of Children. Edited by Abraham Jacobi, M.D., LL.D.; Member American Medical Association, American Pediatric Society, Association of American Physicians, American Climatological Association, Congress of American Physicians and Surgeons, New York Academy of Medicine, New York Pathological Society, New York Obstetrical Society, Consulting Physician Mt. Sinai, Bellevue, German, Babies', Women's Infirmary, Orthopedic, Minturn, and Hackensack Hospitals, etc. An authorized translation from "Die Deutsche Klinik" under the general editorial supervision of Julius L. Salinger, M.D. New York and London: D. Appleton and Company, 1910.

Probably the most valuable portion of the physician's education is the period after he has learned what his own professors have been able to teach him, has completed his practical work in his hospital, and then gives up his few months, or, if he is so fortunate, his year or two, to traveling from city to city studying the methods of other teachers who think differently from those whose opinion he has come to consider as law. To those who can afford it, such a "*Wanderjahr*" is considered a necessary part of the education, and the mental breadth and tolerance so obtained remain with him through his entire career. This is especially so in the case of pediatrics, where so much is done by rule of thumb and by mathematical formulæ. To the young American pediatrist, with his firm impression of top milk feeding, to go to England and see little but diluted whole milk used; to France, where the whole milk is not diluted; or to Germany, where the entire attention is paid to the caloric content of the mixture—even if he may not believe that the results in all cases are quite as good as those of his revered professor at home—the lesson of broad-mindedness is taught. To many students and physicians, however, such travels are not available, and for their sake in the present volume Dr. Jacobi has brought the great clinics of Europe to him. The book is a series of monographs upon subjects pediatric, each by a man whose name is well known far beyond the confines of his own country, but monographs so concise and yet so comprehensive that the subject is covered with most excellent completeness. In many parts of the book opinions are expressed which differ radically from those held in this country, as, for example, when Czerny states that an infant two weeks of age should be fed not oftener than once every four hours. Each chapter of the book, however, takes up some aspect of the subject on which the author is considered especially qualified to write; and as the list of authors includes such well-known men as Czerny, Keller, Heubner, Mornti, Finkelstein, Baginsky, and Henoch, a perusal of its pages is an excellent substitute for a tour of the German clinics. It is not a book to be put into the hands of the student. If read before the reader has thoroughly familiarized himself with the teachings of his own school, it would be apt to produce hopeless confusion. To one who is, however, well versed in his own country's theories of pediatrics and anxious to learn in what ways the German authors differ therefrom, but is unable to cross the ocean to find out, the present book is of inestimable value. To the man who has worked in the German clinics, it is fascinating reading, recalling the special peculiarities and hobbies of the various chiefs.

Quain's Elements of Anatomy. Editors: Edward Albert Schäfer, LL.D., Sc.D., F.R.S., Professor of Physiology and Histology in the University of Edinburgh; Johnson Symington, M.D., F.R.S., Professor of Anatomy in Queen's College, Belfast; Thomas Hastie Bryce, M.A., M.D., Lecturer on Anatomy, University of Glasgow. In four volumes. Vol. III.—Neurology, by E A. Schäfer and J. Symington. Parts I and II, eleventh edition. London: Longmans, Green and Company, 1908.

Quain's Anatomy has become too well known during its many editions to require any recommendation to the teacher or student, as it has won for itself its own position as one of the standard text books of the day. Its convenient form, in several small volumes, commends it to the student who has to carry his text book back and forth from the dissecting room, and its careful attention to microscopic anatomy, as well as gross structure, makes it differ somewhat from the usual type of anatomy familiar in the class-room. This characteristic is especially noticeable in Part I of Volume III, which deals with the general structure of the nervous system and the structures of the brain and spinal cord. Under this heading are described not only the gross shapes of the cerebrospinal axis, but the minuter details of the neuron theory and fiber grouping which makes up the present-day science of neurology. Part II contains the descriptive anatomy of the peripheral nerves and the organs of special sense. The books are in no sense dissecting-room guides, but are of especial value to those who wish to know the physiological significance of the structures of the human body, as well as their outward appearance. The illustrations, as in previous editions of the same work, are rather small and tend more toward being objectively accurate than diagrammatically clear. The system of lettering and numbering the various structures, and then explaining the letters and numbers in a footnote, is adopted rather than the less artistic but simpler and more evident one of placing the name on the structure or at the edge of the picture. This leads to considerable loss of time in referring to the plates, and sacrifices usefulness to neatness. The book, however, is an excellent piece of work, and this volume in its two separate parts makes up a thoroughly accurate and trustworthy text-book of neurological anatomy.

Surgical Anatomy. By John A. C. Macewen, B. Sc. in Anatomy and Physiology with Honors, M.B.C.M., with Honors, Fellow of the Faculty of Physicians and Surgeons, Glasgow. Senior Assistant to the Regius Professor of Surgery, Glasgow University; Surgeon to the Elder Hospital, Govan; Assistant Surgeon to the Royal Infirmary, Glasgow, and H. R. H. Princess Louise Hospital, Roseneath; Late Civil Surgeon, South African Field Force. New York: William Wood and Company, 1910.

This is a concise yet connected account of the essential features of surgical anatomy. It will serve as a useful companion to any of the standard text-books on descriptive anatomy; and to the physician or surgeon in general practice it will be more serviceable than the ordinary text-books. The work is well written, well printed, and well illustrated.

Bibliography of Trypanosomiasis. Embracing original papers published prior to April, 1909, and references to works and papers on Tsetse-Flies, especially Glossina Palpalis. Rob.-Desv. Compiled by C. A. Thimm, Librarian, Sleeping Sickness Bureau. Issued under the Direction of the Honorary Managing Committee. London: Sleeping Sickness Bureau, Royal Society, Burlington House, 1909.

The contents of this pamphlet are sufficiently indicated by the title. There are 228 pages, with 1894 titles alphabetically arranged; and the volume is an almost complete list of references to the published works on sleeping sickness. It will be indispensable to all future writers on that subject.

Society Reports.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held on February 21, 1910.

THE PRESIDENT, DR. ROBERT T. MORRIS IN THE CHAIR.

A Case of Typhoid Fever of Unusual Duration.—Dr. RANSFORD E. VAN GIESON of Brooklyn said he had just discharged a case of typhoid fever that had been under his care since September 13, 1909, a period of over five months. When he first saw the case, the initial temperature was 104° and the patient gave a history of having been sick about ten days. After five weeks' illness the temperature dropped to normal, and remained so for ten days. Then it arose to 104° and remained elevated for about a fortnight. After remaining normal for about a week, it again became elevated to 104.5° and altogether there were three relapses of this kind, making this the longest case of typhoid fever he had ever seen. In reply to a question, Dr. Van Gieson said he strongly suspected that these relapses were due to a focus of reinfection in the gall-bladder. Previous to each relapse, the patient had had violent attacks of vomiting with very slight jaundice.

DR. ANTHONY BASSLER mentioned a similar case observed last year. In his case there were three relapses, and the case was of about three months duration. During the attack and first two relapses there were no symptoms of gall-bladder infection, but the last relapse was accompanied with jaundice and bile in the urine, and for some weeks there was a fatty diarrhea, with clay colored stools. The intestinal symptoms immediately cleared up when the fatty intake of food was controlled. It was probable that the gall-bladder was infected early in the history, but that definite symptoms of it did not occur until considerable cholecystitis occurred.

A Case of Puerperal Septicemia with Unusually High Temperature.—Dr. EDWARD WAITZFELDER said that about a month ago a pregnant woman was admitted to Gouverneur Hospital suffering from severe burns of the arm, thorax, and abdomen. These were treated by the open method (exposure to the air), and after a week or ten days, she was taken in labor and transferred to the maternity ward, which was occupied at that time by a number of parturient women. In less than a week after her admission to this ward, five of the inmates developed puerperal septicemia. In one of these cases the temperature gradually rose, with daily remissions, to 108.6° F. 6th day, 108.6° on the ninth day, and finally reached 110° on the 10th day. It has gradually receded and to-day, the 32d day of her illness, it is 98.6° and the prospect of recovery is very good. In spite of this high temperature the patient never complained of thirst, heat, pain, or any feeling of discomfort and in fact the psychosis of the case was more remarkable than the temperature, and at no time did she have the appearance of one severely ill. In this case, the blood culture was negative; but a single examination was made, the patient refusing to allow another vein to be opened. The speaker hoped to have another blood culture made before the termination of the case as he had found that in cases of septicemia with high temperature, repeated examinations are sometimes necessary to recover the organism from the blood. Dr. Waitzfelder said he regarded the high temperature in this case only as a medical curiosity; that it was caused by the action of the toxins on the heat center, that it was in no sense the measure of the amount of inflammation present and that the only scientific importance to be attached to it was the fact that no visceral changes resulted. Except for a slight albuminuria, which lasted only a few days, there was no evidence of the presence of parenchymatous degeneration of the heart, liver, or kidneys; a condition which we would expect to find with high temperature and toxemia. The question as to whether the patient was suffering from streptococcemia or sapremia, that is, whether it was a bacteremia or a toxemia was still under consideration and could only be answered by other blood cultures. The patient who was suffering from the burns, and to whom these infections were attributed, was duly confined and did not suffer from puerperal septicemia.

A Case of Cancer of the Liver with Misleading X-Ray Plate.—Dr. WAITZFELDER reported this case, and showed an *x*-ray picture which had led to the mistaken diagnosis of cancer of the stomach. The patient was a woman of 60, who, when she came under observation two weeks ago was markedly cachectic and gave a history of long-standing gastric trouble, including occasional attacks of vomiting and pain after eating. Upon examination, there was a well marked mass in the epigastrium, just to the right of the median line. This Dr. Waitzfelder was inclined to attribute to a tense condition of the fibres of the rectus muscle, although several other physicians who examined her looked upon it as a malignant growth connected with the stomach. The patient was given a test meal, and the stomach contents were subjected to the usual laboratory tests, with negative results. An *x*-ray picture was taken by Dr. William H. Stewart, which showed a distinct narrowing of the diameter of the stomach, particularly in the region of the lesser curvature. This strengthened the belief that the case was one of cancer of the stomach, and an exploratory operation was done, which revealed a cancer infiltrating the left lobe of the liver, with involvement of the mesenteric and retroperitoneal glands. The stomach, with the exception of a small nodule in the wall of the lesser curvature, was practically normal. The case was interesting, the speaker said, in that the interpretation of the *x*-ray findings were absolutely negatived by the results of the operation.

DR. ROBERT W. EASTMAN, after examining the *x*-ray plate, said that in radiographic pictures of the stomach and intestines, the changes in the position and outline of the organs should be looked upon as relative rather than absolute. In this particular case he thought that the narrowing in the outline of the stomach was due to pressure from without rather than to a growth of the stomach wall itself.

DR. WILLIAM H. STEWART said he agreed with Dr. Eastman that it was sometimes impossible to tell from the *x*-ray picture whether we had to deal with actual involvement of the stomach wall or whether the change in outline was due to pressure from without, in this case the narrowing of the stomach shadow with some irregularity at the upper portion of the line representing the lesser curvature, had been responsible for the opinion given that the growth involved the stomach wall. There was no organ in the body which so frequently changed its relations to the adjacent organs as the stomach, consequently the normal shadows frequently vary. The speaker had now learned that before giving an opinion, one or two confirmatory radiographs should be taken.

The Effect of X-Ray Treatment in a Case of Endothelioma of the Stomach.—The president, Dr. MORRIS, said that some months ago he did a posterior gastroenterostomy to relieve pyloric obstruction in a case of supposed epithelioma. The growth was so extensive in character that a radical operation was deemed inadvisable, but a section was removed and submitted to Dr. Aspinwall Judd, who pronounced it an endothelioma. Under *x*-ray treatment, the growth had apparently disappeared entirely; the patient had gained about 50 pounds in weight and was now practically well, but may have recurrence. Epitheliomata and endotheliomata, Dr. Morris said, simulated each other so closely that they could not be distinguished ex-

cept by the aid of the microscope, and if of the latter type, the growth was amenable to the *x*-ray treatment, it was a fact worth keeping in mind.

Address by the Retiring President.—Dr. Morris, the retiring president, spoke of the high class of work done by this association, which was now recognized as the most active medical society in the city, perhaps in the State. In a large measure, he said, its success was due to the activity and efficiency of its Secretary, Dr. P. Brynberg Porter, and to the constant aim of the Association to restrict its work to strictly scientific channels, avoiding discussions of subjects of non-medical character, and in presenting at its meeting papers and discussions that covered the topics of the day in medicine.

Why We Are What We Are: The Proper Function of the Medical Society.—Dr. Reynold Webb Wilcox, the President-Elect spoke on this subject. After briefly reviewing the work of the association, he said that it did not find the motive for its existence in the dreary level of mediocrity, but in an earnest and successful effort to create a medical aristocracy, in membership, scientific work, and social relations; an association of scientific gentlemen for the uplifting of a gentlemanly science. It was true, he said, that commercialism was rampant in the land. Its influence had been felt in our profession, for the number of students entering the schools was diminishing, and, unfortunately, there was greater proportional loss in institutions whose entrance requirements were highest, whose instruction was most advanced and thorough, whose final tests were the most exacting, and, finally, whose equipment was the best. But so long as medicine continued to be the noblest of professions, men of culture with the best-trained and the best-equipped intellects and the noblest characters would be attracted to it. When it became the most despicable of trades, this association would have ceased to exist.

Dr. Thomas E. Satterthwaite said that the opportunities for usefulness of a medical society were largely in proportion to its numbers, the variety of its members' attainments, their intellectual breadth, the thoroughness with which discussions were conducted, and the extent to which they were brought before the medical public. Of the three larger societies in Manhattan, the County Society, the Academy of Medicine, and the Medical Association of the Greater City of New York—each operated on its own individual lines. Through the County Society, its members were brought into close touch with the administrative branches of the City and State governments, while each County Society was also one of the constituent elements of the State Society, its members being at the same time eligible for membership in the American Medical Association. Our County Society was, therefore, a useful and necessary body. Among other things, it brought together the medical profession in larger numbers than any other, protected them against malpractice suits, published a directory, and through its legislative committee was concerned in securing good legislation and preventing bad. It was a society that every practitioner of medicine should join: not only as a measure of self-protection, but for the maintenance of the public good. The Academy of Medicine was a more exclusive and smaller but more highly specialized organization, with wider activities in a scientific direction. Its library facilities alone were worth the annual dues. The Medical Association of the Greater City of New York was composed of a select body of general practitioners and specialists, who met jointly to hear and discuss papers of general interest. Through its borough branches it brought its members into closer contact than the other two societies. A dominating feature was that it took up for presentation and discussion the open medical questions of the day, in a systematic manner, concentrating on each one the combined experience of qualified members, and invited guests, lay men and lay women. This novel feature, introduced by this society, had now been adopted as a feature of other societies. Dr. Satterthwaite said that the profession demanded a systematic and timely representation of all the positive advances in medical science, presented by the best qualified exponents of each topic, and in the most concrete and intelligible form, with all the side lights obtainable from any source, inside or outside of the medical profession. We had no time to pour indiscriminately over all the medical literature of the day. The plan as outlined was feasible, though the selection was not always an easy task for the president or program committee. Indeed, it was often quite difficult always to secure readers of papers capable of presenting topics both clearly and fairly. All open questions were, of course, amenable to discussion from various points of view. Not long ago, he was present at a symposium in one of the larger societies, where an open question was discussed, and solely from a partisan point of view. Such a performance was a manifest impertinence on the part of those who devised the program. Curiously enough, the best qualified men or women could usually be secured more easily than the less qualified. Such a campaign of education the Greater New York Association was better fitted to conduct than any other metropolitan society. If, on the other hand, topics were admitted to the program in a haphazard way, or a member could have the rostrum for the asking, valuable time would be frittered away listening to the conceptions of an idealist, exploitations of immature or undigested material, assortments of unrelated facts, or statistics of no real value. Dr. Satterthwaite also believed that the membership might with advantage be widened in at least two new directions. He thought the day was near at hand when the larger societies would have to be opened to all legally qualified practitioners of reputable character, independent of sectarianism. Such liberality would certainly be fruitful of much good. Indeed, we were still owing a debt that we ought to pay to the homeopaths and eclectics, for it was through their help and against the concerted action of those within our own ranks that State medical examinations were secured some years ago. Every year we needed the help of all intelligent, legalized practitioners, to secure useful legislation and combat vicious measures, sometimes even to neutralize misdirected energies in our own ranks. Our present influence in the halls of legislation in this State was seemingly threatened by the divided front we maintain there, when with trivial concessions to others not of our fold, our profession of medicine would be more dignified and respected by the community in general. In the interest of the greater good, it was desirable that we should waive minor differences and come together. The sounder and broader the basis of any organization, the better fitted was that organization for a substantial and enduring superstructure.

Dr. Edward W. Lee said he favored admitting to membership in the Association any worthy practitioner of medicine (male or female), as such, but not as an eclectic or disciple of homeopathy or any other pathy. If medicine was a science, then there was no room in it for different sects.

Dr. Morris, referring to Dr. Satterthwaite's suggestion to admit homeopathic and eclectic practitioners as members of the association, thought that any man who was qualified to practice medicine in the State of New York was also qualified to become a member of this association. The responsibility for the character and attainments of the physicians of these schools, he had long thought, rested with the State, under whose authority they practiced. As to the admission of women physicians, Dr. Morris said that he could see no logical grounds upon which they could be excluded.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 28, 1910.

THE PRESIDENT, DR. JOHN E. WEEKS, IN THE CHAIR.

Report of Committee on Public Health.—Dr. JOHN H. HUDDLESTON, chairman of this committee, said that several years ago a committee had been appointed to learn the amount of venereal disease in New York City and to provide some sort of registry. This Committee on Public Health drew up a resolution providing for examination of smears of pus by the Health Department, and this was presented to the Comitia Minora one month ago. The Comitia Minora authorized the Committee on Public Health to ascertain the attitude of the Health Department toward such a resolution. The result was the Department of Health appointed a committee to confer with a similar committee appointed by the Medical Society of the County of New York in order to determine the wisdom of presenting such a resolution. The Comitia Minora authorized the committee to bring this resolution before the County Society. The resolution was that the Medical Society of the County of New York request the Department of Health to prepare for the examination of smears; also that it send to all physicians in Greater New York a letter stating that it was prepared to examine smears of pus for gonococci for the purpose of diagnosis. The Department of Health, after examining the specimen of pus, would send to physicians a circular letter of information as to the care of patients suffering with gonorrhea, syphilis, and chancroids. Further the Department of Health would furnish physicians with cards for the voluntary reporting of these diseases, such cards to be kept by the Department of Health. The cards were arranged to furnish the age, sickness, and social condition of the patient, but would not disclose his identity. It was moved and seconded that the president appoint a committee of three to confer with the committee from the Department of Health. This was carried.

Perineal Prostatectomy.—Dr. PARKER SYMS read this paper with the object of reviewing the subject of prostatectomy in a broad way, giving special attention to a few important lessons which had been learned by him during the last fourteen years. The radical removal of an obstruction was the only satisfactory method, when the case had reached a period demanding active relief. The radical removal of the obstruction was the only means of affording permanent relief. The topical treatment by means of the catheter was never more than palliative, and was more dangerous than a properly performed radical operation. Prostatectomy was the proper treatment for prostatic obstruction. Perineal prostatectomy should be the method of choice when it could be satisfactorily employed. Anatomically the perineal method was the logical one. It was about twice as safe as the suprapubic operation. It was undoubtedly a more difficult operation and this was the reason why some surgeons advocated the suprapubic operation. Perineal prostatectomy, when properly performed, should give perfect ultimate results. It should be performed with a full knowledge and with a strict regard to the important anatomy of the perineum which was a very complex one. The operator should be able to rely upon the sense of touch, as well as the sense of sight. The complete removal of the obstructing gland and a satisfactory preservation and conservation of various important anatomical structures followed a successful perineal prostatectomy. If these two objects were obtained there would be complete relief of all the symptoms of obstruction and a complete restoration of the normal bladder function. During the early days of prostatectomy, they feared tight stricture of the canal and incontinence of urine. A large instrument should be passed through the urethra a few days after the operation, and a full sized sound should be passed into the bladder once or twice during the period of healing. In fact, there was more apt to be an increase of the caliber of the deep urethra than a diminution. Incontinence of urine as a result of perineal prostatectomy should never follow; this depended on making a proper, clean cut through the membranous urethra with division and not ablation of the fibers of the urethral sphincter, and of conservation of the bladder sphincter. If one was able to reach and recognize the prostate within its sheath, and to find the proper line of cleavage so that the gland could be enucleated without much effort, there should be little laceration and no damage to the bladder. The majority of the cases showed a nearly complete incontinence when the tube was removed, but when the patient began to gain control so that he could hold a small quantity of urine, he always felt confident that complete control might soon be expected. One could not be sure that he had completely removed all the obstruction unless he could reach his finger tip well within the bladder neck and sweep it around the circumference. Dr. Syms called attention to one class of cases in which the obstruction was due entirely to a fibrous contracture of the prostrate, difficult cases to operate upon: in removing these prostatic "rings" or "collars" he always feared that he might produce urinary incontinence. It was important to remove all palpable prostatic tissue; otherwise recrudescence might take place. The most important elements in the disease were cystitis, pyelitis, renal insufficiency, and autointoxication. Kidney insufficiency might exist without the occurrence of infection, due to back pressure through the ureters and it played a very important rôle in many cases. Pyelitis acted in a double capacity by its septic poisoning and its influence on the kidney function. There was a septic poisoning and a lack of elimination, conditions which were not cured by removing the obstructing prostate; therefore, the care of these patients should not cease when their wounds had healed, for they required advice and treatment until the inflammation and infection had disappeared. With regard to the preservation of sexual function, Dr. Syms was confident that perineal prostatectomy left this function unimpaired in a large proportion of cases. Some of the patients had regained this function when it had been absent before the operation. Some had apparently lost it as the result of the operation; others had retained the function unimpaired when it existed prior to the operation. The vast majority of Dr. Syms' patients had been practically cured, having regained or retained their full bladder function, not requiring the use of the catheter, and they were relieved of their distressing symptoms, pains, hemorrhage, cystitis, pyelitis, pyuria, and the autointoxication due to kidney insufficiency. The regeneration of these patients in fact amounted to a rejuvination.

DR. HUGH H. YOUNG of Baltimore reported a careful study made of some four hundred cases of perineal prostatectomy. As late as 1900 a recognized authority on prostatic work made the statement that the mortality of prostatectomy was 20 per cent., and he called attention to the marvelous strides in the saving of lives that had occurred since that time, only ten years ago. During this same period the mortality of the suprapubic route had been reduced from 20 per cent. to 6 per cent. while the perineal mortality was about two and a half per cent. This reduction in the mortality was accomplished through a better knowledge of the anatomy and pathology of the cases, and the development of a more scientific technique, with the operations more thoroughly performed. With regard to the end results, very much depended upon the operator and his knowledge of the anatomy and pathology of the

enlarged prostate and upon the employment of a careful and thorough technique. He should not be hurried except in rare instances because of the improved methods of administering the anesthetic. From an anatomical standpoint there were many things which should be respected in the operation, and the first was the sphincters; these muscles were not obstructive and should not be removed unless necessary. The bulb and urethra also should be respected; if one cut into them there would be loss of blood. They should also respect the blood vessels, especially those in the space of Retzius, the nerve supply to the sphincters which had to do with incontinence of urine, and the verumontanum. With regard to the pathology in the simplest form of enlargements, the two lateral lobes, the internal sphincter was entirely intact. Those cases should not be attacked through a suprapubic opening, but through the perineal. In those cases of median enlargements, one might meet with a case in which the lobe projected into the lumen of the urethra. Or one might meet with a pedunculated middle lobe inside the sphincter or trigone, really more easily attacked by the suprapubic route, but it was wiser to attack it through the perineal route. Aberrant growths of the prostate had been met with frequently, and he had seen several cases in which there was an enlarged lateral lobe present which he thought he had removed, but later he had been surprised to find two lobes again present on the side of the urethra. The lateral lobes grew upward behind the bladder into the region of the seminal vesicles. A rare form of enlargement was an hypertrophy of the lateral lobes which projected toward the symphysis pubis; in operating upon such cases one might leave behind enough of the prostate to form a projecting enlargement about the side of the urethra. Dr. Young said there was no ideal technique, and that most of the methods employed had been destructive in nature. He described his technique in detail, and presented numerous drawings and pictures to illustrate his method of performing perineal prostatectomy. Among his 400 cases there had been 14 over eighty years old, and 150 over seventy years old. There had been 13 deaths, two occurring during the first week, two during the second week, six during the third week, two during the fourth week, and one during the eighth week; this last patient was eighty-eight years old. Among these 13 deaths, there were some that could be held against the operation itself. He had been able to get records of 38 patients who had died since being operated upon, the periods varying from six months to several years, and there were several patients still alive. With regard to their sexual powers, 76 patients claimed they were normal before operation; after the operation, 44 claimed themselves to be normal, 10 claimed coitus was possible, and 22 claimed that coitus was considerably impaired. This operation was not a cure for lost manhood. These patients got out of bed on the third day. There were 280 patients who used the catheter before admission, and only three had to return to catheter life after the operation. The percentage of cured cases was 88; almost cured, 9; distinctly improved, 3. There were only two cases that had incontinence of urine, and he recalled the great importance in preserving the sphincters in order not to have incontinence of urine. He had not seen a single case with stricture of the urethra following the operation. The mortality among his first series of 167 cases showed seven deaths; in his second series of 233 cases there were six deaths, making 13 deaths altogether.

Dr. Charles L. Gibson told of the end results of the operation he had been doing for nine years, perineal prostatectomy, simply an intraurethral enucleation; this operation was very simple, very efficient, and a life-saving one. Since employing this operation he had had no deaths and his late results had been very good. It was remarkable how the old gentlemen were rejuvenated after this operation. Many of the operations were those of emergency and not of expediency. The one trap in the operation was the incontinence of urine, a very serious condition. He thought the danger due more to damage to the cut-off muscle than to damage of the sphincter. With regard to the sexual powers, those he operated on were old people and he never thought to ask regarding this matter. He had three or four cases in which fistulæ resulted. So far as he knew none of the patients used the catheter again after the operation.

Dr. Eugene Fuller discussed the paper. A large portion of his remarks were embodied in a paper recently published by him. (See page 569.)

Juxtaepiphyseal Fractures of the Upper Ends of the Humerus and Femur and Their Treatment.—Dr. Fred H. Albee read this paper in which he showed that epiphyseal disjunction at the hip might occur from all degrees of trauma or from none at all. It occurred very largely in the adolescent period, never above twenty-one or twenty-two years and rarely under ten. If there was no intercurrent disease, the only signs to be detected by physical examination were very slight shortening. Abduction and rotation were usually slightly limited. The skiagraph gave the most information. This disclosed a flattened and somewhat mushroomed head, especially on the superior and inner aspect. The condition was liable to be mistaken for various other hip-joint affections. Conditions which contributed to separation were rickets, scurvy, starvation, septicemia, pyemia, syphilis, and prolonged mercurial treatment. An injury which would produce a dislocation in an adult would, in the adolescent, produce a separation of the epiphysis. If the fracture was a fresh one, then manipulation consisting of strong traction, abduction, and marked inward rotation should be tried. The limb should be fixed in a long plaster-of-Paris spica and the part radiographed to see if a good reposition had been secured. However, on account of the uncontrollable upper fragment, the possibility of securing a good reposition was remote and an open operation was usually necessary. In either event, if the fragments were replaced, they could be held perfectly without metal spike or suture by the above-mentioned position of abduction and inward rotation. Thus the fractured end of the neck, which was always displaced forward in front of the head, was thrown backward into apposition with the fractured surface of the head and the unruptured posterior portion of the capsule was put on tension and served as a splint. The element of abduction carried the upper end of the lower fragment under the rim of the acetabulum and prevented all danger of displacement of the lower fragment upward. The inward rotation was the difficult part of this position to hold, and the writer had flexed the knee to a right angle and held it perfectly in this way. Dr. Albee also considered epiphyseal disjunction of the humerus which he stated was an accident of youth and might occur from birth to the twentieth year; the most frequent period was from the tenth to the eighteenth year. The diagnosis of this condition was usually made by palpation, which revealed the normal convexity of the shoulder, due to the presence of the humeral head in the glenoid cavity, thus distinguishing it from a dislocation. The upper end of the lower fragment, somewhat rounded in its contour, could usually be felt under the coracoid process. The crepitus was of a softer quality than in cases of ordinary fracture. Localized pain and swelling were present and a wrinkling of the skin, caused by a hooking of the upper end of the lower fragment into the subcutaneous tissue, was very characteristic. Abduction was especially limited and muscular spasm interfered with all motions. This was the most difficult fracture of the humerus to treat by conventional methods, there being always a strong tendency to

a recurrence of the displacement. The writer carefully explained the reasons for this tendency. Dr. Albee reported a number of cases, upon which, in view of the difficulties in the way of treatment, he had operated successfully. It was his custom to expose the fracture by a large U-shaped incision with its apex about one and one-half inches above the insertion of the deltoid muscle. The skin, fasciæ and deltoid muscle were turned up *en masse*. The fragments were brought into good apposition by strongly elevating the arm forward and slightly outward, so as to come into alignment with the upper fragment. They were then secured firmly with silver wire. The arm was fixed in this position anteriorly elevated horizontally with the humerus rotated inward. The deltoid muscle was approximated by interrupted chromic catgut sutures through its substance and its fascia which had purposely been left adherent. The shoulder and arm were then incorporated, with the elbow fixed at a right angle, in a plaster-of-Paris spica from the wrist to the umbilicus. In view of the cases reported and the clinical observation of a considerable additional number, and the careful examination of a large number of radiographs taken both before and after treatment, the writer felt that the following advantages could be claimed for this method of treatment: 1. This posture relaxed the prehensile or most of the strongest muscles of the shoulder and arm, namely, the pectoralis major, the biceps, the supraspinatus, the coracobrachialis, the strongest part of the deltoid and the subscapularis muscles, and did it more efficiently than the lateral abduction position. 2. The lower fragment was controlled accurately and held very securely. 3. As in the case of a subtrochanteric fracture of the femur the capital fragment could not be controlled on account of its shortness and the pull of the trochanteric muscles; therefore, the lower fragment was placed in alignment with it in strong flexion and abduction. This treatment of the femur had for a long time been accepted and the same mechanical reasons held here. 4. If limitation of motion at the shoulder occurred, this relation of humerus to scapula was the one of selection, both because it was one of usefulness and also permitted the scapulothoracic muscles to functionate the most efficiently. 5. It was a more comfortable position from the experience of Drs. Berry, Orr, and the speaker than the classical position of fixation to the side of the thorax.

A Study of Diphtheria in Children Based on the Treatment of Eight Hundred Cases.—Dr. E. Mather Sill said that diphtheria was one of the most insidious and treacherous diseases they had to deal with, and on account of the great divergence of its clinical manifestations even those with the widest experience could not expect to diagnose every case by clinical means alone; in fact it was possible to do so only in the more typical cases. On the other hand many cases which on culture growth showed bacteria morphologically identical with the Klebs-Loeffler bacillus, the clinical aspects alone would not indicate or lead them to suspect diphtheria, and it was from his studies along this line that he had been prompted to write this paper. The cases he reported were all verified by bacteriological culture growth. His figures covered a period of eight years, the cases being endemic. Of 757 cases under ten years of age, there were 521 pharyngeal, of which 24 were one year and younger, 116 from one to three years, 76 from three to five years, and 265 from five to ten years. There were 166 nasal cases, the youngest being five weeks old: 22 were one year and under, 69 from one to three years, 32 from three to five years, and 43 from five to ten years. There were 70 laryngeal cases: 7 were one year and under, 35 from one to three years, 9 from three to five years, and 19 from five to ten years. Thus in the order of frequency it was pharyngeal, nasal, and laryngeal diphtheria. With a view of comparing the clinical aspect with the bacteriological findings, 155 cases of diphtheria were examined; there were 61 cases of clinical pharyngeal diphtheria with membrane; 36 of these showed the Klebs-Loeffler bacillus present, and in 25 it was absent. There were 72 cases of clinical nasal diphtheria, or a chronic nasal discharge, 41 of which showed the Klebs-Loeffler bacillus, and in 31 cases it was absent. There were 22 laryngeal cases, 18 of which showed the Klebs-Loeffler bacillus, and in 4 it was absent. Of these 155 cases of clinical diphtheria, there were 95 positive Klebs-Loeffler bacilli reports, or 61.3 per cent. Of 127 cases chosen of simple sore throat without membrane, 59 showed positively the diphtheria bacilli with the first culture, 44.75 per cent. Few people were disposed to take the disease. One attack conferred immunity in a large proportion of the cases for the rest of the individual's life, second and third attacks occurring in from 9 to 13 per cent. of cases. Diphtheria was so frequent in early childhood because children were putting all manner of things in their mouths and, also, because they were prone to catarrhal conditions of the nose and throat. The disease might be contracted by direct or indirect contact. The diagnosis of this disease was both clinical and bacteriological, but finding the Klebs-Loeffler bacillus in the throat established the diagnosis. Dr. Sill's experience with antitoxin in the treatment of diphtheria was that it should be given in large doses, and his rule had been for many years to give an initial dose of 8,000 to 10,000 units, irrespective of the age, for cases of ordinary pharyngeal diphtheria, from 5,000 to 10,000 units in nasal cases, and from 10,000 to 15,000 units in laryngeal diphtheria. These doses were repeated in eight, twelve, or twenty-four hours if there was no improvement. The antitoxin should be given in sufficient doses to neutralize or antidote the toxin of the disease, since they now knew that death was due to the toxin. Enough antitoxin should be given to produce a marked change for the better. A physician was never justified in waiting for the bacteriological examination of a culture; he should always administer antitoxin in a clinical or suspicious case of diphtheria and at once. The mortality in these 800 cases had been less than one per cent., and none that died were over two years of age.

Dr. William H. Park related some interesting experiences in the laboratory work connected with the Department of Health and compared the smear and culture diagnosis of diphtheria. It was only in the doubtful cases that cultures were necessary for the sake of diagnosis. He was glad to be able to report that the antitoxin now furnished had more of the protein eliminated. They now met with practically no disturbances following the use of large doses of the antitoxin. The only objection to the giving of these large doses was the expense.

Dr. Charles Gilmore Kerley said that a great deal had been learned concerning diphtheria during the past ten years, and there was one thing in particular that should be impressed upon every physician, that the giving of antitoxin was a safe procedure and should never be left out in the treatment of diphtheria: even when in doubt as to the diagnosis, one should give antitoxin. Two reasons for the present mortality of diphtheria were (1) the gradual onset of the disease misleading the parents into believing the child was not very sick; the child was then allowed to pass by the point when the antitoxin would be of great value; (2) the antitoxin was not given in sufficiently large doses. His practice was to give a large initial dose without much regard as to the age of the patient; he gave as large a dose for a child one year old as he gave to a child five or six years old, and invariably 5,000 units, and with 3,000 repeated at twelve-hour intervals until he was satisfied that the disease was under control. He had never seen any harm done by these large doses.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of April 9, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	738	193
Diptheria	514	46
Measles	1,541	36
Scarlet Fever	826	40
Smallpox	—	—
Varicella	186	—
Typhoid Fever	37	6
Whooping Cough	47	5
Cerebrospinal Meningitis	2	6
Malarial Fever	—	—
Totals	3,891	332

Results Obtained by the Use of the Ultraviolet Rays in Therapeutics.—H. Bordier says that a mercury vapor lamp is superior to the Finsen lamp as a source of the ultraviolet rays. This may be used at a distance or in contact with the tissue to be treated. The time may vary from fifteen minutes to an hour, the average time being fifteen to twenty minutes. An hour's treatment is to be used in cases in which it is not necessary to produce anemia by pressure. When a deeper effect is desired, it is necessary to use the lamp in contact with the surface, and make pressure. This pressure may be obtained by means of a rubber bandage. A long application is not productive of greater destruction than one of less duration. After an hour's treatment there is no benefit in continuing the sitting. The rays penetrate to a depth only slowly, because the superficial layers of cells absorb them. When the author wishes to get a deep-seated effect he gives one sitting of fifteen to twenty minutes, and repeats it after the first eschar has fallen. The treatment is especially beneficial in lupus, the scars being less marked and more supple than after the x-rays. It is beneficial in herpes or trochophyton circinata. In port wine stains and nevi its effect is marked and satisfactory. Here contact and pressure are necessary. In acne it reduces the hypertrophy and stops suppuration.—*Annali di Elettricità Medica e Terapia Fisica.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended April 8, 1910:

THE PATHOLOGY AND DIAGNOSIS OF GALLSTONES AND DISEASES OF THE BILIARY SYSTEM.*

BY HENRY ROTH, M.D.,

NEW YORK.

ATTENDING SURGEON, LEBANON HOSPITAL.

THE exact diagnosis and proper treatment of gallstones and diseases of the bile tract must be based upon a full understanding of their pathology. Up to recent years our knowledge of pathology was based almost entirely upon postmortem findings, which, in the main, represented terminal states and did not show conditions as they existed in the earlier stages of disease. Living pathology, as seen by the surgeon at the operating table, is more interesting, and is of inestimable value in elucidating the symptomatology of disease. There is nothing which contributed more to our knowledge of diseases of the biliary system than the more frequent opportunity of observing living pathology during operations. Nothing makes a more lasting impression upon our minds than a clear demonstration of the existing lesions; therefore, it cannot be urged too strongly that whenever it is possible patients be followed by their attending physicians to the operating table, where they can see the cause of many obscure symptoms and realize the futility of former treatment. One who sees a gangrenous appendix, with rapidly spreading peritonitis eighteen hours after the onset of symptoms, will not again wait, after making an early diagnosis, for the development of a localized abscess. Nor will he attempt to cure so-called gastralgia, dyspepsia, indigestion, and hyperacidity with pepsin, hydrochloric acid, bicarbonate of soda, or gastric lavage, when at the operation there is revealed to him as the cause of all these symptoms a gall-bladder packed with calculi and adherent to pylorus, duodenum, and colon. A few such observations will convince any one that gallstones may be present without jaundice, in spite of the still existing and widespread belief that such a state of affairs is impossible. A study of conditions revealed at the operating table will demonstrate the futility of attempting to dissolve calculi in a cystic gall-bladder. It will show how misleading is the sense of security after the passage of a large calculus through the rectum, when subsequent operation demonstrates many more calculi in a gall-bladder, adherent to all surrounding structures and connected by a fistula with some portion of the gastrointestinal tract. The cure of such a condition is connected with a great deal of danger, whereas the removal of calculi from an otherwise intact gall-bladder is, in the hands of the experienced, one of the safest operations. There is nothing which will impress one more with the dangers of gallstones than to see at operation a carcinomatous gall-bladder filled with calculi, which, by their long continued irritation, have brought on a hopeless condition. Knowing these dangers, the physician in the future will not wait, temporize, and advise operation only as a last resort, but will seek surgical relief at an earlier stage of the disease, when operation is safe and is followed by speedy and permanent relief. Realizing the great importance of pathology as the foundation of our knowledge of disease, we will endeavor to outline briefly the various changes as they occur in the course of gallstones and gall-bladder diseases and their relation to the various symptoms which they produce. Furthermore, for the satisfactory understanding of the symptomatology of diseases of the biliary system, it is essential to recall the close relationship which exists between this system and such neighboring structures as the stomach, duodenum, and pancreas. This relationship is embryological, anatomical, and physiological, and the pathology of one frequently produces changes in the other, as, for instance, the frequent involvement of the pancreas secondary to stone in the common bile-duct, or pyloric obstruction, due to adhesions between stomach and gall-bladder.

For purposes of illustration, we will cite the histories of a number of patients selected from a series operated upon by me at Lebanon Hospital in the course of eighteen months; this period includes our three terms of service during the last three years. Our list includes the various diseases of the gall-bladder, from simple noncalculous cholecystitis to carcinoma. Many of the cases are typical illustrations of lesions as they are found by the surgeon, and it must be stated at the outset that no two patients present the identical pathological or clinical picture.

There were 32 operations performed upon 30 patients, 9 of whom were men and 21 women.

The pathological conditions found at the time of the operation were: acute cholecystitis, 7 (died, 1); acute gangrenous cholecystitis, 1; acute perforating cholecystitis and general peritonitis, 1 (died, 1); acute perforating cholecystitis and pericholecystic abscess, 1; post-typhoid cholecystitis, 1; empyema of the gall-bladder, 5; hydrops of the gall-bladder, 2; chronic cholecystitis, 8; carcinoma of the gall-bladder, 1; noncalculous cholecystitis, 3.

Cholecystostomy was done in 27 cases and cholecystectomy in 3. Pain was a symptom in every case, jaundice in only 8 of the 30, and a mass was palpable in 10 of the patients. One patient died as the result of acute perforation of the gall-bladder and general septic peritonitis. The history of this patient will be given in detail in another part of this paper. The second fatal case was that of a man, 50 years old, who was operated upon during an acute attack of cholecystitis. He gave a history of twelve attacks of biliary colic within six years. On account

*Read at a meeting of the Medical Society of the Borough of the Bronx, December 8, 1909.

of a very large abdomen, the operation was one of the most difficult in this series, and was interrupted several times by respiratory difficulties caused by the anesthetic. Cholecystostomy was followed by a mucous fistula and repeated attacks of retention. At a subsequent operation, several months later, the sinus was explored with the result of finding another calculus in the neck of the gall-bladder. Removal of this calculus was followed by a free flow of bile, but the patient, unfortunately, developed bronchopneumonia and died ten days after the operation. The other patient operated upon twice was a man, 33 years old. A cholecystostomy was done for acute cholecystitis, and several calculi were removed. This was followed by a free flow of bile lasting several weeks. The fistulous tract continued to discharge a mucopurulent fluid which persisted until it was explored. At the second operation no calculi were found, and the only cause for the sinus which could be demonstrated was a mass of granulation tissue which filled a contracted gall-bladder. Removal of this was followed by a free flow of bile and final closure of the sinus. The patient is now enjoying perfect health.

Normal bile in the healthy individual, with unobstructed flow, is comparatively free from bacteria, although it is looked upon as a good culture medium for some. When the natural flow is interfered with, for one reason or another, stagnation of bile occurs, and this favors the growth of bacteria in the residual fluid. The microorganisms are brought to the liver from the intestine by way of the portal circulation, although infection may ascend from the duodenum along the common duct. In passing through the liver the virulence of bacteria is greatly diminished and the resulting infection is of a mild degree, giving rise to a catarrhal condition of the gall-bladder, the so-called lithogenous or stone forming catarrh. The microorganisms most frequently found are the colon and typhoid bacilli, although others, such as the staphylococcus, streptococcus, and pneumococcus, may be present. The catarrhal inflammation may persist for some time and remain as a chronic noncalculous cholecystitis, which is not at all rare. In most instances, however, as the result of this catarrhal inflammation we have exfoliation and degeneration of epithelial cells, a deposit of cholesterine and lime salts, which, with the addition of bile pigment, enter into the composition of gallstones. Thus we see that for the development of cholelithiasis it is essential to have a partial obstruction to the flow of bile and a mild infection of the gall-bladder. Whether or not other factors, such as heredity, a special diathesis, or a peculiar composition of the bile, due to faulty metabolism, have any bearing upon the development of gallstones, is not so well known. It is conceded by most observers that typhoid fever is one of the most important etiological factors in cholelithiasis, and the typhoid bacillus has been found in the center of gallstones many years after an attack of enteric fever.

Cholecystitis is a well known complication of typhoid fever; it is more common in women than in men, and is usually caused by the typhoid or colon bacillus. It may be serous, purulent, or perforating, and, according to Ashhurst (*American Journal of the Medical Sciences*, April, 1908), calculi are found only in 19 per cent. of the cases. It usually develops in the second or third week of typhoid, but may occur shortly after convalescence, as in the following instance:

Case I.—Hospital No. 21,262. Isaac B., 48 years old, was admitted to the hospital about six weeks after the onset of typhoid fever, from which he recovered in about four weeks. Nine days before admission, after a hearty meal, he was suddenly taken ill with severe pain all over the abdomen and chest, the pain being worse on the right side and radiating toward the back. The pain was paroxysmal in character, coming on every few minutes and lasting but a short time. He became jaundiced and his stools were clay colored. On admission his temperature was 102.4° F., pulse 110. Blood examination showed 28,800 white blood cells, with 85 per cent. polymorphonuclears. Jaundice was very marked. There was pain and tenderness and board-like rigidity of the upper right rectus muscle. The abdomen was distended and tympanitic. On account of rigidity a mass could not be felt. Operation revealed a distended gall-bladder, containing a glairy mucopurulent fluid, but no bile. Bacteriological examination of this fluid showed bacilli having the characteristics of the colon bacillus. Calculi were not found in the gall-bladder or ducts. Six days after cholecystostomy bile was present in the stools, his jaundice cleared up, and he left the hospital cured. The jaundice was probably due to a cholangitis, which was the result of the infection extending by continuity from the gall-bladder to the other parts of the bile tract. When cholecystitis, especially of the perforating variety, occurs during typhoid it may be very difficult to differentiate it from intestinal perforation.

That pregnancy plays an important rôle in the etiology is borne out by the fact that the disease is more common in women than in men, and that the majority of women who have gallstones have borne children. The disease is extremely rare in childhood, and more than half of the cases occur in persons past forty years of age. Gallstones are found in individuals in all walks of life, among the poor as well as the rich. The stones may be single or multiple, and in size range from fine gravel to that of a large egg. Where many concretions are present they are usually found in groups of different sizes, showing different periods of development; the largest calculus is usually near the neck of the gall-bladder. The color varies from a light yellow to almost black, depending upon the amount of bile pigment which enters into the composition; pure cholesterine stones are almost white in color. They are round or ovoid, smooth and faceted, or rough and irregular, as, for instance, the mulberry-shaped stones of recent origin, which are usually very dark and soft, and are composed mainly of bile pigment. Single stones are usually round and have a rough surface. The usual site of development is in the gall-bladder, and it is here that most of them are found, although they may be present in any portion of the biliary tract or in all combined. Calculi in the hepatic ducts are rare, and are usually found in connection with calculi in the common duct.

Gallstones may be associated with only very slight changes in the gall-bladder; there may be only a moderate degree of inflammation of the mucosa, and this may be present even though the calculi have existed for a long time. In most cases, however, the calculi sooner or later produce changes which are the result of irritation which they cause as foreign bodies or as obstructing agents to the normal flow of bile. As the result of irritation small erosions are produced which, in the presence of microorganisms, are points of lessened resistance, and thus inflammation of the gall-bladder or cholecystitis develops.

This may also occur if the normal flow of bile is interfered with by a calculus in the neck of the gall-bladder or by one trying to pass through the cystic duct. A calculus so situated may at first not interfere with the flow of bile, but may later by pressure cause edema of the mucous membrane and then suddenly block the edematous duct. The products of inflammation which result from this cannot escape, and the gall-bladder becomes distended with serum, mucus, or pus, depending upon the kind and degree of infection. Examination of the contents of the gall-bladder may show them to be sterile, even in the presence of pus, but this may be due to faulty methods of examination or to the fact that the infection resulted from microorganisms of lessened virulence. (Deaver, *American Journal of the Medical Sciences,* January, 1908.) Cholecystitis may be acute or chronic, serous or serofibrinous, purulent or gangrenous.

In acute catarrhal cholecystitis the gall-bladder is distended, its walls are at first thin, then become thick. The mucosa is red and edematous, and the serosa may be covered with fibrin. The bile is thick and dark and contains a good deal of mucus. If the inflammation subsides sufficiently to allow the escape of the products of inflammation, the gall-bladder grows smaller and returns to its former size, but this does not signify that the patient is cured. The pathological condition just described was present in a number of cases, but the following is a typical example:

Case II.—Hospital No. 22,886. Arthur S., 39 years old, was admitted five days afer the onset of his illness. He gave a history of typhoid fever at the age of 18, and an attack of colic seven years ago. Five days ago he was suddenly seized with crampy pains all over the abdomen, vomiting several times the same evening. The bowels were constipated. The pain became gradually localized to the right side of the abdomen, was less severe, but quite constant. On admission the temperature was 102° F., pulse 104. There was moderate pain, tenderness, and rigidity over the middle of the right rectus muscle. Operation revealed a distended, tense gall-bladder, with thick walls, containing inspissated bile and one nonfaceted calculus. Cholecystostomy was followed by uneventful recovery.

If the infecting agent is more virulent, the inflammation proceeds to pus formation and a purulent cholecystitis or empyema of the gall-bladder results. In this condition the gall-bladder is usually distended, the walls are decidedly thickened, the pus may be slight in amount, may be thin or thick, bile stained or not, and in some cases very foul, as in the following case:

Case III.—Hospital No. 19,967. Mary B., 70 years old, the mother of five children, was admitted to the hospital on August 24, 1907. She stated that about two weeks ago she had very frequent watery stools, accompanied by vomiting. The vomiting consisted of gastric contents, later on becoming slightly bile stained. Her bowels moved every thirty minutes, and she vomited four to seven times in the course of a day. A week ago she began to complain of abdominal pain, associated with extreme tenderness on the right side. About this time the diarrhea and vomiting ceased. On examination a distinct mass was felt in the right upper quadrant, of a very obese abdomen. The mass extended from below the costal margin nearly to the umbilicus. It was well circumscribed, round, and freely movable. Tenderness and rigidity were present, but not marked. The temperature on admission was 104° F., pulse 104, but before the operation she had a chill, followed by a temperature of 106.8° F. and a pulse rate of 144. Blood examination showed 14,500 white blood cells and 78 per cent. polymorphonuclears. Operation revealed a very much enlarged gall-bladder, bluish in color, and adherent to the omentum and colon. A large quantity of very foul pus and very dark, almost black, bile was evacuated, with 29 calculi, which were black in color, faceted, and smooth, the largest being found in the neck of the gall-bladder. Cholecystostomy was followed by recovery.

Empyema of the gall-bladder may develop in a contracted, a carcinomatous, or in a cystic gall-bladder, as in the following case:

Case IV.—Hospital No. 23,621. Emma M., 39 years of age, married, was admitted on October 10, 1908. One year ago she had an attack of sharp pain, localized over the region of the gall-bladder and accompanied by vomiting and constipation. The pain continued for almost two weeks. Three weeks ago she had a similar attack. This time the pain continued for ten days. Two days before admission she had still another attack, similar to the previous two. The attacks always began at night, and were never associated with jaundice. Her temperature was 100.6° F., pulse 112. The abdomen was very large and pendulous. There was moderate pain, tenderness, and rigidity in the right upper quadrant of the abdomen. A distinct mass was felt just below the right costal arch, moving with respiration. Operation revealed a distended, large, and tense gall-bladder, containing a mucoid fluid mixed with flakes of pus, and one large ovoid stone impacted in the neck of the gall-bladder. Cholecystostomy was followed by uneventful recovery.

Associated with empyema of the gall-bladder there may be cholangitis as well as localized or general peritonitis, with or without adhesions. If the infection is very virulent, the cholecystitis may be associated with ulceration, gangrene, or perforation. Ulceration may be slight or very marked. Necrosis may involve only the mucosa, or it may extend to the peritoneum, terminating in perforation and general peritonitis, even though there be but few calculi. The following two cases will serve as illustrations:

Case V.—Hospital No. 19,265. Mary V., 26 years old, mother of two children, was admitted on June 4, 1907, one day after she first felt an uneasy sensation in the upper part of the abdomen. This sensation gradually developed into pain, which grew steadily worse and radiated to the nape of her neck. She vomited twice on the first day and had chilly sensations. Jaundice was not present at any time. Her temperature was 102° F., pulse 120, and leucocytes 19,500. Tenderness and rigidity were very pronounced over the upper part of the right rectus muscle. Just below the right costal margin a distinct mass was seen to move up and down with respiration. Incision through the right rectus exposed a large, tense, and very adherent gall-bladder, which contained pus and a few soft mulberry-shaped stones. The greater part of the mucous membrane was necrotic, black, and loose, and was therefore removed. Cholecystostomy was followed by recovery.

Case VI.—Hospital No. 20,630. Ulysses K., 43 years old, was admitted to the hospital with a diagnosis of acute appendicitis. Four years ago he had an attack of illness similar to the present one, but not quite so severe. During the evening of the day before his admission he felt some distress after eat-

Number	Hospital No.	Name	Age	Sex	Married or Single	Duration and History of Disease	Symptoms
I	18,750	M. S...	29 yrs.	F.	M.	Recent; one child	Chill; pain; vomiting; rigidity; mass; temp., 101.4; pulse 112; W. B. C., 10,400.
II	19,240	Y. F...	28 yrs.	F.	M.	One month ago an attack; several children; youngest 3 weeks old.	Duration one day; colic; vomiting; tenderness; rigidity; temp., 98; pulse, 84.
III	19,265	M. V..	26 yrs.	F.	M.	Recent; 2 children	Chill; pain; vomiting; rigidity; mass; temp., 102; pulse 120; W. B. C., 19,500.
IV	19,967	M. B..	70 yrs.	F.	M.	5 children	1 week duration; diarrhea; vomiting; chill; pain; tenderness; rigidity; mass; temp., 106.8; pulse, 144; W. B. C., 14,500.
V	19,976	A. H..	33 yrs.	M.	M.	One year of abdominal pain; pyrosis	Tenderness.
VI	19,985	W. F...	45 yrs.	F.	M.	Five children; 2 years ago had an attack	Two weeks ago abdominal pain right side and shoulder, pain sharp in character; tenderness; rigidity; temp., 100.6; pulse, 104; W. B. C., 16,000.
VII	20,338	E. C...	42 yrs.	F.	M.	Five children; 4 to 5 attacks in 2 years; lost 50 lbs. in 6 months; jaundice.	Duration 2 weeks; pain, sharp cramp-like, radiating to scapula; vomiting; sl. jaundice; rigidity; tenderness.
VIII	20,416	H.....	38 yrs.	F.	M.	Several children	Duration 3 years, attacks of pain; vomiting; jaundice; tenderness; no mass.
IX	20,630	U. K..	43 yrs.	M.	M.	An attack 4 years ago	Duration 1 day; chill; pain; tenderness all over abdomen; gen. peritonitis; temp., 103; pulse, 130.
X	20,955 26,137	F. Sch.	33 yrs.	M.	M.	Recent	Duration 2 days; cramps all over abdomen; vomiting; tenderness; rigidity; mass; temp., 103.2; pulse, 124; W. B. C., 17,600.
XI	21,162	I. B...	48 yrs.	M.	M.	Recent typhoid	Duration 9 days; pain; tenderness; rigidity; jaundice; temp., 102.4; pulse, 110; W. B. C., 28,800.
XII	22,376 25,171	J. B...	50 yrs.	M.	M.	In 6 years had 12 attacks of biliary colic	Slight tenderness.
XIII	22,886	A. S...	39 yrs.	M.	M.	Typhoid at 18 years; 7 years ago had colic	Duration 5 days; pain; vomiting; tenderness; rigidity; mass; temp., 102; pulse, 104.
XIV	22,909	B. K..	26 yrs.	F.	M.	One year's duration; jaundice 9 weeks ago and 5 weeks ago.	Duration 3 weeks; jaundice disappeared; loss in weight; mass.
XV	23,295	K. F..	36 yrs.	F.	M.	Several children; pain in gall-bladder region and vomiting.	Duration 1 week; jaundice; clay-colored stools; tumor.
XVI	23,437	J. L...	25 yrs.	F.	M.	Three severe attacks in 11 months; lost 40 lbs. in 4 years.	Duration 4 days; colic; tenderness; slight pain; no rigidity.
XVII	23,456	M. G..	32 yrs.	F.	M.	Had 2 attacks in 3 years	Duration 2 weeks, pain.
XVIII	23,621	E. M..	39 yrs.	F.	M.	One year's duration; several attacks of biliary colic.	Duration 2 days; colic at night; pain; tenderness; rigidity; mass; temp., 100.6; pulse, 112.
XIX	24,027	M. B..	28 yrs.	M.	S.	Several attacks of severe colic and vomiting in 18 months.	Last attack 2 months ago; now has no pain, tenderness, rigidity, or mass.
XX	24,291	M. R..	32 yrs.	F.	S.	16 mos. ago colic at night; 4 attacks, constant pain for 9 months.	Had jaundice; clay-colored stools; slight tenderness.
XXI	24,738	Mrs. S.	61 yrs.	F.	M.	For 2 years had crampy pains	Duration 8 days; colic; vomiting large movable mass.
XXII	25,593	S. F...	26 yrs.	F.	M.	Duration 17 months; 3 months after childbirth; colic at night; vomiting; several attacks.	Two days ago had another attack; physical examination negative.
XXIII	25,652	H. H..	44 yrs.	M.	M.	For 6 to 7 years irregular pain in upper part of abdomen; nausea.	Attacks every month, lasting 2 to 3 days; some tenderness; nausea.
XXIV	25,759	E. G...	26 yrs.	F.	S.	Long history of frequent pain and vomiting; fullness of stomach.	Three weeks ago; cramps; vomiting; fever; rigidity; tenderness.
XXV	25,870	J. R...	31 yrs.	F.	M.	Several children; duration one year; vomiting; pain.	Duration 1 day; colic; vomiting; mass in gall-bladder region; tenderness; rigidity; temp., 101; pulse, 100.
XXVI	26,296	M. A..	42 yrs.	F.	M.	Two years' duration; several attacks every 10 weeks.	Almost daily pain for 5 weeks; tenderness in epigastrium.
XXVII	26,464	G. B...	45 yrs.	M.	M.	Abdominal pain for 5 to 6 months; radiating to right shoulder and back.	More frequent attacks in last 2 to 3 months; fever; some tenderness in gall-bladder region.
XXVIII	26,680	M. D..	32 yrs.	F.	M.	Several children; 9 months ago had pain; vomiting; jaundice.	Three weeks after child birth; 3 days ago; colic; vomiting; tenderness; rigidity; mass; temp., 103.6; pulse, 112.
XXIX	27,120	Mrs. W	58 yrs.	F.	M.	Four children; duration 3 weeks	Duration one week; fever; tenderness over gall-bladder region; temp., 105; pulse, 98.
XXX	27,313	R. W..	21 yrs.	F.	M.	Typhoid; baby 9 months old; 2 months ago colic; vomiting.	Duration 8 days; colic; vomiting; jaundice; tenderness; rigidity; temp , 100.2; pulse, 90; W. B. C., 16,000.

ing. Upon going to bed he had a severe chill, followed by vomiting and intense abdominal pain, which kept him awake the entire night. The pain continued the following day and was very pronounced when he arrived at the hospital. His temperature was 103° F., pulse 130. His face was drawn and anxious, typical facies Hippocratica. His abdomen was distended and very rigid. Tenderness was very pronounced all over the abdomen, but mostly so over the right half, from the epigastrium down to Poupart's ligament. Incision over the appendix was followed by the escape of a large quantity of bile-stained fluid, which was odorless. The appendix and intestine were coated with a fibrinous exudate. The appendix was thought not to be the cause of the peritonitis. The gall-bladder was therefore exposed and found to be covered with dark gray patches, one of which had perforated, allowing the escape of some dark, bile-stained fluid. The gall-bladder contained three small calculi and a quantity of tarry-looking bile; owing to the desperate condition of the patient, the gall-bladder was drained and

Pathology	Contents of Gall-Bladder	Treatment	Result	Remarks
Ac. cholecystitis	117 calculi	Cholecystostomy	Recovery	
Ac. cholecystitis	Calculi	Cholecystostomy	Recovery	
Ac. gangrenous cholecystitis	Calculi	Cholecystostomy	Recovery	Gangrene of mucosa; removed.
Empyema of gall-bladder	Very foul pus; 29 calculi	Cholecystostomy	Recovery	Biliary fistula for some months
Chr. cholecystitis	Several large yellow mulberry calculi.	Cholecystostomy	Recovery	
Empyema of gall-bladder	Few large calculi and pus	Cholecystostomy	Recovery	
Chr cholecystitis; small gall-bladder	8–9 calculi	Cholecystostomy	Recovery	Calculi in ducts; patient very stout.
Ac. cholecystitis	Bluish calculi	Cholecystostomy	Recovery	
Ac. perf. cholecystitis; gen. septic peritonitis.	3 calculi	Cholecystostomy	Died	
Acute cholecystitis	Few soft calculi	Cholecystostomy	Recovery	1st, drained bile; mucous fistula 18 months. 2d, curet. and cautery.
Post-typhoid cholecystitis	No calculi; glairy mucus	Cholecystostomy	Recovery	
Ac. cholecystitis; contracted gall-bladder.	26 calculi	Cholecystostomy	1st, recovery; 2d, died.	Calculus in cystic duct at 2d op'n; chr. muco-pur. fist'la; dr'd bile.

Chr. cholecystitis	Many calculi	Cholecystostomy	Recovery	
Empyema of gall-bladder	Full of pus; one large calculus	Cholecystostomy	Recovery	
Chr. cholecystitis (non.-calculous)	Thick glairy bile-stained mucus	Cholecystostomy	Recovery	
Hydrops of gall-bladder	One large calculus	Cholecystostomy	Recovery	
Cystic gall-bladder	Many calculi, glairy mucus (no bile)	Cholecystostomy Cholecystectomy	Recovery Recoevry	Drained bile.
Chr. cholecystitis	36 calculi; glairy mucus (no bile)	Cholecystostomy	Recovery	Appendicectomy done
Chr. cholecystitis (non-calculous)	Thick bile and glairy mucus	Cholecystostomy	Recovery	Simultaneously, pyloric adhesions.
Chr. cholecystitis	many calculi	Cholecystostomy	Recovery	Dense adhesions.
Empyema of gall-bladder	Pus and 31 calculi	Cholecystostomy	Recovery	
Chr. cholecystitis	Few calculi	Cholecystostomy	Recovery	Adhesions to omentum.
Chr. cholecystitis (non-calculous)	Thick bile; (no calculi).	Cholecystostomy	Recovery	Adhesions to omentum.
Cholecystitis (perforating); pericholecystic abscess.	No calculi	Cholecystectomy	Recovery	
Acute cholecystitis	2 calculi	Cholecystostomy	Recovery	
Ac. empyema of gall-bladder	112 calculi	Cholecystostomy	Recovery	Pus contained staph. pyogenes aureus.

completely surrounded by gauze and a drain introduced into the pelvis. In spite of active stimulation, death resulted from general septic peritonitis within a few hours after the operation and within less than thirty-six hours after the onset of the pain.

Gangrene may be circumscribed and result in a pericholecystic abscess, as in the following case:

Case VII.—Hospital No. 26,680. Margaret D., 32 years old, the mother of several children, was admitted on August 9, 1909. Nine months ago she had a severe attack of epigastric pain, accompanied by frequent vomiting and jaundice, which persisted for five weeks. Three days before admission to the hospital, and a little less than three weeks after her last child was born, she had another sudden attack of epigastric pain. The following morning the pain recurred, and was accompanied by vomiting of much green material. The pain and vomiting persisted for the next two days, the pain radiating to the lumbar region and down toward her pelvis. On admission her temperature was 103.6° F., pulse 112. The entire right side of the abdomen was distinctly

tender, especially in the upper part. Rigidity was marked in the upper right quadrant and over the right flank. Under this rigid area a distinct mass was palpable. On opening the abdomen a mass of thickened omentum was exposed, which was adherent to the lower surface of the liver. Under this a pericholecystic abscess was found surrounding a very small contracted gall-bladder with thick walls. The fundus of the gall-bladder was gangrenous and perforated. On attempting to bring the gall-bladder, which was not more than an inch in length, to the surface, it broke away and left but a small portion in the depth of the wound. There were no calculi in the gall-bladder or in the duct. Drainage was followed by uneventful recovery. It is not unlikely that this patient passed a calculus through the common duct nine months ago, at the time of the attack which was accompanied by pain and jaundice of five weeks' duration.

Hydrops, or cystic gall-bladder, is the sequence of acute cholecystitis. It results after absorption of bile pigment from the inflammatory exudate, which cannot drain out of the gall-bladder because a calculus obstructs the cystic duct. In this condition the gall-bladder may be enormously distended, its walls may be thick or very thin, and it contains a clear mucoid fluid which, as the result of reinfection, may become purulent, resulting in empyema. The following case will serve as an illustration:

Case VIII.—Hospital No. 24,738. Mrs. S., 61 years old, mother of several children, gave a history of frequent cramp-like pains two years ago. Eight days prior to her admission she was suddenly seized with sharp, agonizing cramps and vomiting. The pain at first was in the region of the stomach and liver, and later became more diffuse, radiating toward her back and shoulders. At the time of admission it was localized over the right iliac and lumbar regions. A movable tender mass, the size of a fetal head, was felt in the right lumbar and iliac regions, and seemed to be continuous with the edge of the liver. A diagnosis of kidney tumor had been made in this case, but on account of the absence of any urinary symptoms and the history of cramp-like pains in the region of the stomach some years before, and the fact that during the early part of the present illness there was some febrile disturbance, a diagnosis of cystic gall-bladder seemed more appropriate. On opening the abdomen a very large distended gall-bladder was exposed, which contained many calculi and a clear mucoid fluid. The cystic duct was occluded by a firmly impacted calculus. Cholecystectomy was followed by speedy recovery, and she left the hospital in less than two weeks after the operation.

If the cystic duct is not completely occluded, the products of inflammation drain into the hepatic and common ducts, producing a cholangitis, which may be acute or chronic, and if the infection is very virulent, may terminate in multiple abscesses of the liver. Acute pancreatitis is another condition which may result from this spreading infection.

An acute attack of cholecystitis may be followed by chronic inflammation of the gall-bladder, a condition present in most gall-stone cases which are not associated with acute symptoms. In this condition the gall-bladder is usually contracted, the walls thick, there may be ulcers which may perforate into some neighboring organ, producing a fistula or an abscess. The cystic duct may become stenosed and the gall-bladder may have hour-glass contractions or diverticula. All forms of cholecystitis are associated with pericholecystitis, resulting in adhesions to contiguous structures. Such adhesions are most marked with the acute suppurative, but may be pronounced even with chronic noncalculous cholecystitis. The adhesions may involve the pylorus, stomach, duodenum, colon, or omentum, singly or all combined, and may produce obstruction in any one of the affected hollow organs. The following cases will serve as illustrations of chronic cholecystitis and pericholecystitis:

Case IX.—Hospital No. 19,976. Alfred H., 33 years old, was admitted on August 28, 1907. For the past year he has been subject to attacks of pain, localized to the upper part of the abdomen, which usually started four to five hours after a hearty meal, and which were relieved by vomiting. Bowels were constipated, and between the attacks of pain he had frequent pyrosis. He was never compelled to remain in bed, nor does he believe that he ever had fever during these attacks. On examination, slight tenderness was elicited on deep pressure along the right costal arch and in the epigastrium, but there was no rigidity, nor was a mass palpable. Incision exposed a tense gall-bladder with thickened walls, containing a dark, viscid fluid and several bright yellow mulberry-shaped stones, the largest of which was cylindrical, and was taken from the cystic duct. Cholecystostomy was followed by rapid recovery.

Case X.—Hospital No. 26,296. Mary A., 42 years old, mother of one child, was admitted on July 5, 1909. Two years ago she had an attack of sharp pain in the region of the stomach, radiating to both shoulders. The attack began in the middle of the night, and was accompanied by nausea. For one year following this she suffered from a dull pain in the abdomen, and then had a similar attack, but more severe. For the past year she has been having attacks about every ten weeks, most of them occurring at night. For the past five weeks she has been having pain almost daily, but never vomited until a few days ago. She had chills and fever with some of the attacks, but was never jaundiced. Appetite is very poor and bowels are constipated. There is tenderness in the epigastrium, but no rigidity or tumor. At the operation the gall-bladder was found adherent to the omentum, and contained a few soft calculi and some thick, tarry-looking fluid. Cholecystostomy was followed by uneventful recovery.

Case XI.—Hospital No. 25,759. Miss Emily G., 26 years old, was admitted to the hospital on May 12, 1909, and gave a long history of frequent attacks of pain and vomiting and fullness of the stomach. Three weeks ago she had a sudden attack of crampy pains in her abdomen, accompanied by nausea, vomiting, fever, and general malaise. Later the pain became most marked in the right side of her abdomen, and was constant. There was slight rigidity of the right rectus, and some tenderness just above McBurney's point. The gall-bladder was found buried in a mass of dense adhesions involving the liver, pylorus, duodenum, colon, and omentum. After considerable difficulty a small portion of the gall-bladder fundus was exposed and incised. The gall-bladder was contracted, had thick walls, hour glass contractions, and diverticula. It contained five large and a number of small calculi in thick, dark bile. The operation was extremely difficult, it being impossible to do anything but introduce a tube into the deep-seated and immovable gall-bladder. The operation was followed by marked relief of all her symptoms, although when last seen she still had a fistula discharging bile.

A calculus may pass from the gall-bladder through the cystic into the common duct, and from there into the intestine through the papilla. If the calculus is small this may readily occur, but if too large to pass the papilla it remains in the common duct, and may be associated with an inflammation of the duct, completely obstructing the flow of bile. As the inflammation subsides swelling of the mucosa will diminish, and the flow of bile will be reestablished. Reinfection of the bile passages is very frequent with calculi in the common duct, resulting in contraction of the gall-bladder. The common duct is dilated and the walls are thick; the hepatic ducts are also dilated and frequently contain concretions which form secondarily. Pressure of a calculus in the common duct will cause chronic pancreatitis, a condition which is not at all uncommon. Adhesions may develop between the common duct and duodenum, with perforation and escape of calculi. Large calculi which are occasionally passed per rectum have usually escaped through such a fistula. A very large calculus may produce intestinal obstruction. Other complications of common duct stones are cholangitis, liver abscess, usually multiple, pylephlebitis, and various manifestations of a general systemic infection. Calculi may be present simultaneously in different parts of the biliary system, and several of the pathological lesions described may be present at the same time. The number of such combinations of lesions is very large, as pointed out by Richardson (*Boston Medical and Surgical Journal*, June 17, 1909, Vol. CLX., No. 24, page 768).

Cholecystitis may occur without calculi, it may be acute or subacute, but usually is chronic and is associated with adhesions to nearby organs. The acute form may even be gangrenous or perforating, and may cause general septic peritonitis. The pathology of noncalculous cholecystitis is not unlike that described in speaking of the variety associated with calculi. The following is the history of a patient with chronic noncalculous cholecystitis:

Case XII.—Hospital No. 25,652. Hyman H., 44 years old, was admitted on May 4, 1909. Nine years ago he was operated upon for chronic appendicitis. For the past six or seven years he has had irregular pains in the upper part of the abdomen. During the last year he had attacks of sharp, sticking pain over the region of his liver and stomach. These attacks were accompanied by nausea and general weakness. The attacks occcurred about every month and lasted from two to three days. He never vomited, nor was he ever jaundiced. The present attack is of a week's duration. With the exception of some tenderness in the upper right quadrant and epigastrium, there were no other signs of significance. At the operation the gall-bladder was found adherent to the pylorus. The walls of the gall-bladder were decidedly thick; it contained a thick, dark, bile-stained fluid, but no calculi. Cholecystostomy was followed by recovery, which, however, was interrupted by another attack of pain four months after the operation, probably due to reformation of adhesions between gall-bladder and pylorus.

Benign tumors of the gall-bladder are extremely rare, and of these, according to Moynihan ("Gall-Stones and Their Surgical Treatment," 1905, page 131), papilloma is the most common. Cancer of the gall-bladder, which is more common, may be looked upon as the most serious result of chronic gallstone irritation. An overwhelming majority of cases of primary carcinoma of the gall-bladder are associated with calculi, while in cancer of the gall-bladder secondary to cancer of some other organ calculi are rarely found. The neoplasm is usually near the fundus, and may develop upon an ulcer, irritated for a long time by calculi. When the diagnosis is made the disease is usually too far advanced for complete eradication. Associated with carcinoma there may be a papillomatous mass in the gall-bladder containing many calculi in its meshes, as in the following case:

Case XIII.—Hospital No. 23,295. Katie F., 36 years old, the mother of several children, was admitted on August 31, 1908. As far as it could be ascertained, her illness began about three months ago with a dull and constant pain in the epigastrium. For the past two months she has had attacks of tearing pain in the region of the gall-bladder and crampy pains in the epigastrium immediately after eating. During this period she vomited several times. One week ago she became jaundiced following an attack of pain. Her stools were loose and white in color at different times. She lost about 20 to 30 pounds in weight in the past three months. At the time of the examination there was no tenderness nor rigidity in the region of the gall-bladder, but an oblong tumor mass was palpable below the right costal arch and under the upper part of the right rectus muscle, extending downward for about two inches, and being about 1½ inches wide. Incision through the right rectus exposed a hard and nodular gall-bladder containing calculi. Despite the fact that the liver was studded with a number of hard, yellow umbilicated nodules of metastatic nature, the gall-bladder was extirpated in the hope of relieving the pain, which was so pronounced a symptom. The gall-bladder was completely filled with a papillomatous mass, growing from the fundus, and containing many almost white, irregular calculi. The patient left the hospital about four weeks after the operation and died at her home several months later. On microscopic examination, the tumor was pronounced an adenocarcinoma.

From a study of the foregoing remarks it is apparent that gallstones may produce symptoms by irritation, migration, or obstruction. When calculi are present in a gall-bladder which is but slightly changed, the symptoms will rarely point to the gall-bladder, but rather to some disturbance of digestion which may manifest itself by distress or fullness in the epigastrium. Kehr ("Die Interne und Chirurgische Behandlung der Gallenstein Krankheit," München, 1906) claims that the so-called gastralgias are in 95 per cent. of cases to be attributed to gallstones. Infection of the biliary system is associated with most of the cardinal symptoms of inflammation, and the prominence of the symptoms depends upon the location of the lesion and the virulence of the infecting agent.

Pain is the most important and most constant symptom, and, according to Richardson, the absence of pain of any degree is incompatible with a diagnosis of gallstones. The pain varies in situation and degree; it may range from a dull, heavy, or burning sensation to the sharp pain of biliary colic which frequently starts abruptly in the middle of the night. The pain is in the upper part of the abdomen, radiating to the chest, back, or right scapula. It is usually very severe and agonizing, and may induce collapse. It may stop just as abruptly as it started. It may last from a few minutes to many hours, and be followed by pain of less degree, localized to the right hypochondrium. It may recur at intervals of weeks, months, or even years. Whether

or not biliary colic is caused by the mere passage of a calculus through the ducts or to infection of even a mild degree, as Kehr believes, or to both acting together, is still an open question. Certain it is that it is directly due to spasmodic contractions of the distended gall-bladder or ducts in their endeavor to expel some of their contents, whether they be calculi or the products of inflammation. So-called biliary colic may therefore occur in cholecystitis without calculi. Tenderness is not as constant a symptom as pain. It is most marked in acute infections, and its maximum point of intensity corresponds to a point slightly to the left and below the junction of the right ninth rib and its cartilage. It may be present all over the right hypochondriac and epigastric region. In cases without acute symptoms some tenderness may be elicited during inspiration by deep pressure below the free border of the ribs. With pain and tenderness there is usually rigidity of the upper part of the right rectus muscle; the extent and degree depend upon the degree of inflammation; it may be diffuse in the earliest stages of infection, and then become more localized, and be most marked in the region of the gall-bladder. It is most pronounced in the severe forms of acute cholecystitis, with diffuse peritonitis, and is usually absent in the chronic form.

With biliary colic the temperature may be normal, but if there is a rise in the temperature it quickly returns to normal with the end of the attack. With the onset of cholecystitis the temperature may reach 101° or 102° F.; in suppurating and gangrenous cholecystitis it may be preceded by a chill and reach as high as 103° to 105° F., although it may be but slightly above normal, even though the gall-bladder be filled with pus. The reasons advanced by Mayo ("Keen's Surgery," Vol. III., page 997) for the absence of marked systemic reactions in infections of the gall-bladder are that the gall-bladder has few lymphatics and no lymph glands, and that the products of inflammation are under slight tension in an easily distensible organ. In chronic obstruction of the common duct there is frequent reinfection of the biliary ducts, resulting at times in cholangitis and multiple abscesses of the liver. The temperature, therefore, shows an abrupt rise to a high degree, 105°-107° F., preceded by a chill, associated with profuse sweating and followed by a marked drop to normal or subnormal. These exacerbations recur at varying intervals, and may continue for several weeks. With a rise in the temperature there is a corresponding acceleration of the pulse rate and leucocytosis.

Nausea or vomiting is present with biliary colic, which it frequently relieves. Vomiting may be present at the onset of acute cholecystitis, and is then usually the result of reflex irritation; it may be a symptom of chronic gallstone disease, especially where pyloric obstruction results from adhesions between the gall-bladder and pylorus or duodenum.

A swelling or tumor may be present if the gall-bladder is markedly distended by calculi or the products of inflammation. In acute cholecystitis, hydrops, or empyema, the gall-bladder may attain a very large size and the tumor may extend down into the right iliac fossa. It is usually pear-shaped, continuous with the edge of the liver, and moves with respiration. In very thin patients it may be visible and movable from side to side. In some cases of acute cholecystitis a tumor cannot be felt either because the swelling extends inward and backward under the liver or because tenderness and rigidity interfere with satisfactory palpation. With stone in the common duct the gall-bladder is usually contracted and cannot be felt. In carcinoma the gall-bladder is enlarged and presents a large, firm, nodular tumor, especially if the liver is involved as well. In many cases of gall-bladder disease there is a tongue-like projection of the liver, known as Riedel's lobe. The liver is enlarged when cholangitis is present, but in the average gall-stone patient there is no reason for enlargement.

Jaundice is not a constant symptom. Contrary to a widespread belief, gallstones may be present without jaundice, although the absence of this symptom has long been construed as an indication of the absence of gallstones. According to most observers, it occurs only in a small percentage of cases. It may be very marked or so faint that only the sclera are stained. It may be persistent or temporary, or may be intermittent; at one time it may be very pronounced, while at another it may be hardly perceptible. When it is present it is usually associated with bile pigment in the urine and itching of the skin. Jaundice is due to an obstruction to the natural flow of bile, caused by inflammatory swelling of the mucosa of the hepatic or common ducts. Obstruction to the flow of bile may also be caused by a plug of inspissated mucus and bile, an impacted calculus in the hepatic or common ducts, a tumor of the papilla, pressure of a tumor from without, or by torsion of the ducts caused by adhesions. With a stone in the gall-bladder or cystic duct, jaundice need not be present, but when it does appear it is usually due to an inflammatory swelling of the common and hepatic ducts, which results from an extension of infection from an existing cholecystitis, or from pressure upon the hepatic or common ducts by a large calculus in the cystic duct. With calculi in the hepatic duct, jaundice may or may not be present. Calculi in the common duct are associated with jaundice in about two-thirds of the cases. The jaundice is marked if the calculus is impacted, and intermittent or slight if it acts as a ball-valve. In carcinoma of the gall-bladder jaundice may or may not be present; when it occurs it is due to secondary involvement of the hepatic and common ducts, and is pronounced and progressive. In carcinoma of the common duct or papilla, jaundice occurs very early and is very pronounced. Marked jaundice is usually associated with clay colored stools, owing to the failure of bile to reach the intestine.

In cases without acute symptoms a careful history often reveals the fact that the patient had typhoid fever at some time in the past. A woman may state that her first symptoms or first colic occurred soon after childbirth. There may be a history of chronic indigestion, eructations of gas, nausea, or vomiting, which did not yield to the usual therapeutic measures. There may be a history of repeated attacks of abdominal pain, possibly coming on at night, which were diagnosed as gastralgia and were associated with slight jaundice, biliousness, and flatulence. Many of these symptoms are due to adhesions between the gall-bladder, on the one hand, and the stomach, duodenum, or colon, on the other, and may be present even with noncalculous cholecystitis. To enable one to make an intelligent prognosis, it is very important to diagnose the exact pathological lesion or lesions which are present; therefore we will briefly consider the clinical picture presented by the various complications of gall-stones.

Acute cholecystitis, with or without calculi, usually starts with abdominal pain which may have

all the characteristics of biliary colic. Pain may be preceded by a chill, especially in the suppurating or gangrenous variety, and be followed by a rise in the temperature and pulse rate. The temperature varies, being only slightly elevated in the mild, but may reach 107° F. in the more acute cases. In mild cases it quickly returns to normal; there is usually hyperleucocytosis, nausea, or vomiting, and obstinate constipation. With pain there is diffuse tenderness and rigidity. A few hours after the onset of symptoms tenderness and rigidity are localized to the gall-bladder region. At this time a tumor or swelling may be palpable which may be the distended gall-bladder, with or without adhesions or a Riedel's lobe. The tumor may reach to or below the level of the umbilicus, and usually moves up and down with respiration. When cholecystitis occurs during the course of typhoid fever the symptoms are apt to be masked by those of the primary disease. In acute cholecystitis jaundice is only present if the infection spreads to the hepatic or common duct or by pressure upon these ducts. When a complicating cholangitis is present, jaundice is very pronounced.

Chronic cholecystitis, with or without calculi, is characterized by symptoms referable to the stomach or duodenum. Temperature and pulse are usually normal. As a rule there is no palpable tumor, but there may be some tenderness in the region of the gall-bladder on deep pressure. Jaundice is usually absent, but may be present to a slight extent. There is some soreness or a sensation of fullness in the epigastrium. There may be a history of previous attacks of colic, nausea, eructations of gas, occasional vomiting, and flatulence.

The most characteristic symptom of stone in the cystic duct or of hydrops of the gall-bladder is a tumor in the right hypochondriac region, which may be very large, tender or not, and is usually freely movable. There is a history of previous attacks of pain. Jaundice is rarely present.

The symptoms of a calculus in the common duct depend upon whether the obstruction is complete or not, or whether there is an acute infection present. In either case there is a history of previous colics or pain. When obstruction is complete—a condition which is rare—jaundice is very pronounced and constant. If infection is present, the temperature shows the characteristic features described above. The abrupt rise of temperature is preceded by pain and chills, is associated with profuse sweating and followed by an abrupt drop to normal or subnormal. These paroxysms recur at varying intervals, and are accompanied by symptoms of systemic infection Nausea or vomiting and marked loss of weight and strength are usually present. The gall-bladder is contracted; therefore a tumor is not present. If there is a tumor in the region of the gall-bladder, with deep jaundice, it usually indicates malignant disease, and not calculi, especially if there is a history of previous attacks of pain, or if the tumor were present before jaundice appeared. With calculi in the common duct the stools are clay colored and the urine contains bile pigment.

In carcinoma of the gall-bladder there may be a history of gallstone disease. A tumor develops which may not be associated with pain because the cystic duct becomes obstructed gradually or not at all. Loss of weight, cachexia, metastases, and ascites are usually present.

Biliary colic and acute cholecystitis may be simulated by renal colic, Dietl's crises, lead colic, the gastric crises of locomotor ataxia, acute appendicitis, perforation of a gastric or duodenal ulcer, acute pancreatis, intestinal obstruction, or epigastric hernia. In renal colic the pain usually radiates down the ureter toward the scrotum, vulva, or thigh, and there are urinary symptoms, such as painful or frequent micturition, hematuria, or pyuria. Tenderness is usually most pronounced in the costovertebral space.

With Dietl's crises a movable kidney is palpable, and there may be urinary symptoms. The history and well-known condition of the gums will aid in the diagnosis of lead colic; likewise a good history and other well-known symptoms will readily point to the gastric crises of locomotor ataxia, although there is no reason why a tabetic patient might not have gallstones. Acute appendicitis might simulate acute cholecystitis, especially if the appendix or some part of it is situated high up under the liver, but in appendicitis, the initial pain, as a rule, does not radiate to the back or right shoulder, and is usually less severe. Tenderness and rigidity are at a lower level, while in cholecystitis they are most pronounced over the upper part of the right rectus, even if the gall-bladder is very much below its usual site.

Appendicitis is always associated with a rise in the temperature, while in biliary colic there may be no systemic disturbance. In fact, acute appendicitis, as a rule, is associated with more marked constitutional disturbance than cholecystitis, unless the latter be of the gangrenous or perforating variety. In perforation of a gastric or duodenal ulcer, the pain may come on just as suddenly and be quite as excruciating as in biliary colic, but a history of previous gastric hemorrhage or blood in the stools, as well as pain after eating, will point to the stomach or duodenum. The abdomen will be scaphoid, and tenderness as well as rigidity, at first most marked in the epigastrium, will later become most pronounced in the right iliac fossa. These signs may be associated with entire absence of liver dullness.

In acute hemorrhagic pancreatitis there is very pronounced collapse, violent pain in the epigastrium, radiating to the back, and cyanosis of the skin, with very pronounced constitutional symptoms. The obstinate constipation present at the onset of acute cholecystitis may simulate intestinal obstruction, but in the latter condition the pain is rarely in the gall-bladder region; vomiting is more frequent and persistent and constipation does not yield to the usual medical treatment. Epigastric hernia can be recognized by the presence of a small bulging in the upper part of the recti muscles.

Tumors of the gall-bladder may have to be differentiated from movable kidney, renal tumors, echinococcus cysts or other neoplasms of the liver, and carcinoma of the colon or pylorus. A movable kidney can be recognized by its position, outline, and the fact that it can be replaced into its normal position. Renal tumors have the outline of a kidney, are usually in the lumbar region, and, as a rule, do not move with respiration, and are more deeply situated than gall-bladder tumors. The history is very different, there may be hematuria or pyuria and bulging in the flank. Tumors of the liver are rarely preceded by the symptoms suggesting gallstone disease. Carcinoma of the colon is associated with symptoms of obstruction, a different history, cachexia, and at times wih ascites. Car-

cinoma of the pylorus is characterized by obstruction to the passage of food from the stomach, cachexia, hematemesis, and the presence of lactic acid and stagnating particles of food in the stomach contents.

Stone in the common duct, which is usually associated with jaundice and fever, may have to be differentiated from catarrhal jaundice, hypertrophic cirrhosis, carcinoma of the liver, malaria, pyelophlebitis, chronic pancreatitis, or tumors of the pancreas. In catarrhal jaundice there is a history—possibly the result of indiscretion in diet—of an acute gastrointestinal inflammation, not preceded by pain, and associated with slight systemic disturbance. It occurs in young persons, and at times is epidemic. In hypertrophic cirrhosis, the size of the liver, the long duration of the disease, the enlarged spleen, with but little pain and slight systemic disturbance, all point to the liver as the seat of the disease.

Carcinoma of the liver, usually secondary, causes a nodular tumor, ascites, cachexia, and none of the febrile symptoms so well known with stone in the common duct. The chills, high temperature, and sweats of malaria occur with more regularity. In malaria jaundice is not so pronounced, the stools are not clay-colored, hyperleucocytosis is absent and the plasmodium may be present. There is no history of pain, and there is usually splenic enlargement present.

Pyelophlebitis is a condition usually secondary to some intraabdominal infection, the liver is enlarged and tender, jaundice is not so deep and is not preceded by colics, nor are the stools clay colored. The differential diagnosis between calculus in the common duct and chronic pancreatitis is very difficult, and, at times, is impossible. The presence of the Cammidge reaction may simply point to involvement of the pancreas secondary to cholelithiasis. Carcinoma of the pancreas is not preceded by a history of colics or pain, is not associated with rigors or sweats, but by rapid and marked emaciation, persistent and deep jaundice, clay-colored stools, a distended gall-bladder, large liver, cachexia, and possibly ascites.

Gallstone disease is very common, but in a very large proportion of cases is only recognized after it has produced lesions, some of which are of very grave consequence. The diagnosis, in a typical case, characterized by all the cardinal symptoms, is simple, but the diagnosis of the exact location of the calculi, and the nature of the lesions produced secondarily, is frequently very difficult. Furthermore, the multiplicity of lesions which may exist in an individual case makes an exact diagnosis even more difficult.

A correct diagnosis can result only from a good history, accurate observation, and proper interpretation of the symptoms and signs. In the diagnosis of obscure cases a good clinical history is more valuable than any other factor. It should be taken with patience and care, for many times it sheds more light upon the case than even a painstaking physical examination.

Finally, in the obscure cases of long standing, when all available means of diagnosis have been exhausted and all reasonable therapeutic measures have failed to relieve, exploratory laparotomy, in the hands of the experienced surgeon, is a justifiable procedure, which frequently results in speedy and permanent relief.

409 East One Hundred and Fortieth Street.

END RESULTS FOLLOWING OPERATIONS FOR PROSTATIC OBSTRUCTION.*

By CHARLES H. CHETWOOD, M.D.,

NEW YORK.

PROFESSOR OF GENITOURINARY SURGERY, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO BELLEVUE HOSPITAL, NEW YORK; CONSULTING SURGEON TO ST. JOHN'S HOSPITAL, LONG ISLAND CITY.

In attempting to discuss with you the end results of prostatectomy, with the purpose of gaining an unbiased opinion for the enlightenment of the profession at large as to the dangers, complications, and permanent results of this important operation, it is desirable that we should if possible, evolve a general theory of current opinion and a basis upon which we can fairly draw conclusions. Otherwise, we may approach this subject from so many points of view that the result must lead to uncertainty and confusion, and some of our reports be over- and others undervalued. Could we reach definite views in this matter, they would be extremely useful to us. To this end I would suggest the omission of such generalities as "50 successive and successful operations upon the prostate without a death," or "the selection of an operation is determined by the rate of its mortality"; or, as one surgeon phrased it in a flight of oratory, endeavoring to favor the perineal method of approach as against the suprapubic, that "it was needless to get into a house by way of the roof when it was possible to enter by the front door."

End results, on the whole, are good, bad, and indifferent: a good result in one case might be a bad result in another, and *vice versa*. Death follows operation as a result of the gravity of the operation, plus the inability of the patient to sustain it. The unexpected existence of cancer may be a determining cause of death in some of our prostatic operations. The occurrence of septic thrombosis and pulmonary embolism may close the scene abruptly and carry off an otherwise promising case. The condition of the kidneys has an important bearing upon the chances of any patient who is about to undergo a severe surgical procedure, and is of maximum importance in the case of operations upon the urinary organs.

Such after-complications as swollen testicles, stone in the bladder, incontinence of urine and fistula, and a persistence of a large amount of retained urine, necessarily bring discredit upon the operation, and sometimes render the second state of the patient worse than the first; and the frequency and cause of their occurrence call for careful investigation in the consideration of the subject under discussion.

The operation is performed primarily for prostatic obstruction and the resultant conditions of cystitis, retained urine, and urinary sepsis are overcome only when this primary condition is successfully remedied by operation. When these unfavorable conditions are abolished, the operation is a complete success, but when the after-result is accompanied by the development of any of the complications mentioned, the satisfactory result of the operation is materially affected. Yet, a good end-result is necessarily relative, and should be estimated according to condition before operation and the features peculiar to that particular case. Thus, a patient who has two kidneys irreparably damaged

*Read at a meeting of the Surgical Section of the New York Academy of Medicine, March 4, 1910.

to an advanced degree, who, on account of complete or incomplete retention of urine, is compelled to rely upon the use of the catheter, may have to be operated upon on account of his inability to introduce the catheter when otherwise operation might be considered inexpedient. Such a case should not be considered as a bad result, even though there was a continued necessity for the use of the catheter following operation, due to the existence of a chronically inflamed, thickened, and trabeculated bladder. The greater our experience becomes, the more we appreciate the bearing of these various features upon the question of a successful issue in any one case.

On consulting my available records I find a collection of 100 operations for prostatic obstruction. From these are excluded several cases of cancer of the prostate in which only a conservative operation was attempted, with the knowledge that the cancer involved not only the prostate, but the floor of the bladder as well. I have included three cases of cancer (two of which proved fatal), because at the time of operation the malignancy appeared to be confined to the prostate alone in two of them, and in the other it was discovered afterwards, when the rectovesical wall gave way and a large rectovesical fistula resulted prior to death. In examining the histories of these 100 cases I find much of interest from my own personal experiences—too much, indeed, to dwell upon here, as it would consume an unlimited length of time. I will confine myself, therefore, briefly to those facts which have a direct bearing, so far as these records are concerned, upon the dangers, complications, and results accompanying the different methods of operation by which the 100 cases were treated.

I am frank to state that these records, which cover a period of about ten years, reveal an evident change of ideas and practice with respect to the methods adopted in operating, and suggest the resemblance to a man who is unsettled in his religious belief and changes his faith several times. Thus, I started as a Methodist, later became a Presbyterian, and have now settled down as a Universalist. In other words, most of my early operations were done by the galvanocautery technique; later, the cases were divided between this and perineal prostatectomy, according to the indication for one or the other of these methods. In recent years, however, the cases have been divided between various methods of operation, including that of suprapubic prostatectomy, which is undoubtedly the method of choice in some cases.

These 100 cases represent all types of prostatic obstruction, from the prostatic bar and concentric collar to the symmetrically enlarged prostate, anterior to the bladder, and intravesical enlargement, median and bilateral. Among these 100 cases there have been eight deaths, and I have included in these all fatalities which have occurred within eight weeks after operation. Two of these deaths were patients with cancer of the prostate, and the operation performed was perineal prostatectomy. Both of these deaths occurred within three weeks after operation. One death occurred from pulmonary embolism in a case of suprapubic prostatectomy during the third week following operation, when the patient was apparently convalescing and sitting up out of bed. Two deaths occurred from septic thrombosis, one of which followed a perineal prostatectomy six weeks after operation, when the patient had left the hospital, and the other a galvanocautery prostatotomy, within the two weeks following the operation. Two deaths, from shock and severe hemorrhage, followed closely after the operations, which were suprapubic prostatectomies. One patient died from renal insufficiency following galvanocautery prostatotomy.

The rate of mortality favors perineal prostatectomy as compared with suprapubic, but a more careful analysis of the cases is required to demonstrate this fact indisputably. I believe this conclusion is in keeping with the consensus of opinion, although the rate of mortality of the high operation, like that of the perineal, is being lowered by improved technique and more rapid operating. The question of mortality cannot be intelligently discussed in reviewing any one man's records, or by comparing such records with those of several other men, unless a careful analysis and fair comparison of the different types of cases be made. And this, I understand, is not the principal topic to be discussed in the subject before us.

As to final results, I have believed for some time past, and still believe, that the galvanocautery operation is ideal for certain types of prostatic obstruction: namely, stenosis of the vesical orifice as a result of old, chronic inflammation of the urethra and bladder, and kindred types of concentric prostatic obstruction of the collar or bar variety, which cannot be enucleated with the same degree of facility as a lobular enlargement of the gland anterior to the bladder neck or an intravesical growth.

I will not consume time in discussing the question of galvano-prostatotomy through a perineal opening, as I now believe that this operation is limited in its field to special cases of the type already named. In earlier days I was inclined to use this technique more generally, but have found that it is not suitable for prostatic enlargement of symmetrical hypertrophy, or bilateral and median growths, except in a very limited way. And yet, in looking over my records, I find some early cases of very considerable prostatic enlargement that were treated by galvanocautery prostatotomy through a perineal opening, that are among the best results. I recognize, however, that these are the exceptions and not the rule, and should not be cited in favor of this technique in that particular class of cases.

I find one striking case that was operated on in June, 1901. The patient, 66 years old, had a considerably enlarged prostate, a bilateral intravesical growth, the two lobes being about the size of birds' eggs. The patient was in very bad general physical condition, and was not considered a good subject for prostatectomy. Cystoscopic observation revealed a pyelonephritis on one side, and a large jet of pus could be seen exuding from one ureter. This patient made a remarkable recovery as a result of the galvanocautery operation through the perineum. He is alive to-day, being 75 years old. He completely empties the bladder, and the pyelonephritis has subsided to the extent of not impairing to a marked degree his general health. His weight increased after the operation some 15 or 20 pounds, and he has retained ever since his improvement in general condition. This case, in spite of its favorable outcome, does not prove the utility of this technique in the class of cases in which there is much enlargement of the prostate, as several other cases of the same type did not present such favorable end-results; and I will dispose of the question of galvano-prostatotomy for prostatic obstruction by summarizing the cases as follows: 10 per cent.

presented tuberculous involvement of the prostate or bladder, and all of these were unimproved; 90 per cent. had residual urine, varying from one ounce to complete retention; 10 per cent. had no residual urine; but all the cases presented complete stenosis of the neck of the bladder to the extent of not allowing the entrance of the finger. All of them presented the usual symptoms of prostatism, namely, dysuria, urgency, frequency, difficulty or precipitancy of urination.

Exclusive of the tuberculous cases, 85 per cent. have been cured or much improved, and 15 per cent. only partially improved. This refers to the dysuria, the disappearance of the residual urine, and the elongation of the urinary intervals or the facility or greater ease of urination.

As to the complications, swollen testicle has occurred in about 10 per cent. of the cases, and this almost invariably in patients who gave a history of one or more previous attacks of the same trouble; incontinence of urine in about 10 per cent., amounting to a slight dribbling in about 5 per cent., and to a more or less continual flow in 5 per cent., these latter being the early cases, when the galvanocautery incision was not properly gauged and was carried too far beyond the internal sphincter, encroaching upon the external. Stone in the bladder has occurred in none of these cases, and perineal fistula in none except the tuberculous cases and the cancer case already referred to.

I have been able to follow many of these cases, the earliest ones dating back to 1900 and 1901, up to the present day, and in all the cases reported as "improved" or "cured" that have been traced, the result has been permanent, except in those in which there existed prostatic enlargement anterior to or behind the vesical outlet, in which relapses have occurred, and subsequent prostatectomies been performed, either by myself or other surgeons.

Of the perineal prostatectomies, the end-results have been relatively satisfactory so far as the functionating power of the bladder, the elimination of residual urine, and the elongation of the urinary intervals, are concerned. Of course, in all such cases the result after operation must be compared with the previous condition of the patient, and in those cases in which the bladder has been clean before operation, where the kidneys are in fairly good condition, the result naturally has been very much better than in cases with extensive and deep bladder inflammation and damaged kidneys.

It is difficult to state exactly what the end-result has been in such a miscellaneous collection of cases, without a proper analysis of each one, and, therefore, we can better consider the question by referring to the particular untoward occurrences that have resulted in some cases.

So far as the residual urine is concerned, I believe in the vast majority of cases, as shown by these personal records, as well as by those of others, that when the prostatic obstruction is removed completely, whether it be by the perineal or suprapubic route, that the functionating power of the bladder is returned. Inflammation, however, may remain for an indefinite period, and with permanent contracture of the bladder, cause an undue frequency of urination, and sometimes a continuation of dysuria, which, however, is more or less controlled by bladder lavage and after-treatment. Incontinence of urine has occurred as a mild dribbling in about 4 per cent. of the cases. There has been no instance of post-operative calculi in any of these cases.

There have been three cases of rectovesical fistula, one cancerous, that died within three weeks following the operation, and in the other two the rectal fistula persisted over six months after operation, and one of the patients, a feeble old man over 70 years of age, succumbed to the operation for relief of his after-condition. One case of simple perineourethral fistula was permanently cured by a slight operation. Swollen testicle occurred in about the same percentage (10) as in the galvanocautery operation, and notably in patients who had had previously the same trouble.

In the suprapubic cases there have been about the same percentage of postoperative swollen testicle as followed the perineal operations, and here, again, there was invariably a previous history of similar trouble. In several cases with such history, when that precaution was taken to do previously or simultaneously a double vasectomy, no complicating orchitis followed the prostatic operation.

As to incontinence of urine, there has been no case among the suprapubic operations of my records, except where the suprapubic operation followed a previous perineal prostatectomy. There were two such cases, and the incontinence of urine ensued owing to the fact, I believe, that the integrity of both the internal and external sphincters of the bladder were impaired by the double operation. No case of stone in the bladder is recorded as having followed any of the suprapubic operations. No rectal fistula has resulted, and no suprapubic fistula has persisted beyond a reasonable period. The end results in all of the surviving cases, so far as the functionating power of the bladder, the elongation of the urinary intervals, and the complete emptying of the bladder are concerned, have been generally satisfactory.

There is something to say of interest in this discussion with regard to the cases of other operators that fall into our hands. It is quite natural that one's bad results do not find him out directly, but often are discovered in the hands of another surgeon. This has been my experience with a number of cases, and I doubt not that some of my own unsatisfactory results have been revealed to others. On this point I have taken some account of the cases that have drifted in my direction, having been operated upon elsewhere. I have seen within the past year fully a half-dozen cases of incontinence of urine operated upon, all of them by perineal prostatectomy; two cases of stone in the bladder, one a suprapubic and the other a perineal prostatectomy; a case of perineal prostatectomy that combined all of the complications of swollen testicle, incontinence of urine, perineal fistula, and stone in the bladder; a case of rectovesical fistula following perineal operation; a patient operated on by the perineal route from whom both lateral lobes had been removed, and who still had complete retention of urine requiring the removal, suprapubically, of a large middle lobe the size of a walnut. This is the case already referred to that suffered from incontinence of urine following the latter operation.

As to the question of virility as applied to all of the different operative procedures, I cannot make any very definite statement, as it seems that some patients claim that they still retain their sexual powers and others lose them. In these latter, in some instances their powers have already declined prior to the operation.

To summarize briefly these personal experiences and resulting convictions: The operation of pros-

tatectomy, perineal or suprapubic, is a complete operation, attended by excellent results in favorable cases, and relatively good results in less favorable ones, according to the condition existing before operation.

The mortality rate is, on the whole, not high, and is being lowered by improved methods of treatment before and after operation and better technique. The mortality rate may favor somewhat the perineal route, but the excellent after-results following the suprapubic method cannot be excelled. And it would seem that certain of the untoward after-complications, namely, those of recto-vesical fistula and urinary incontinence, occur in a certain percentage of the perineal operations, and seldom, if at all, after primary suprapubic operation. The other complications, swollen testicle and stone in the bladder, occur about equally in a small percentage following all the different methods.

Residual urine entirely disappears when the prostate is completely removed and the vesical orifice cleared of obstruction. The continued existence, after operation, of subjective symptoms, such as dysuria and urinary frequency, depends upon the condition of the bladder before operation, and such persistence is determined by the nature and extent of the bladder lesion.

On the whole, few operations in surgery can show a better progress in the last decade than can that of prostatectomy when its limitations and results are fairly regarded.

If caution is called for, it is to discourage too much operative fervor in favor of any one method to the extent of overlooking the existence of different types of prostates and the favorable results attained by other methods, and to condemn undue haste in disturbing the peaceful lot of some aged patients, whose conditions are too satisfactory to warrant the risk of surgical intervention.

100 East Thirty-fourth Street.

TWENTY-FOUR, FORTY-EIGHT, AND SEVENTY-TWO-HOUR PNEUMONIAS IN CHILDREN.*

By LE GRAND KERR, M.D.,

BROOKLYN, N. Y.

VISITING PEDIATRIST TO THE METHODIST EPISCOPAL (SENEY) HOSPITAL; TO THE WILLIAMSBURGH HOSPITAL, AND THE SWEDISH HOSPITAL IN BROOKLYN, N. Y.; CONSULTING PEDIATRIST TO THE E. N. Y. DISPENSARY.

When at the last meeting of this society, I discussed the excellent paper of Dr. Hills and remarked that "lobar pneumonia might be of very short duration in childhood, ending by crisis within seventy-two, forty-eight, or even twenty-four hours" the writer thought that he was stating a somewhat generally accepted truth. However, the pains and labor with which my discussion was discussed gave rise to the birth of this paper.

The onset of a disease is frequently so characteristic that this becomes an important factor in the diagnosis. This is especially so in the case of lobar pneumonia. The fact that a child in perfect health is attacked suddenly with vomiting and a chill or chilly sensations, which is accompanied by a rapid rise of temperature to 103° F. or over, is suggestive of pneumonia. And if after a few hours, the child is visibly ill with a dry, hot skin, flushed cheeks, and a much accelerated respiration, it is much more than suggestive. But however suggestive such a symptomatology might be, it is the minuter consideration of the individual symptoms and their association that concerns us.

In the presentation of the clinical reports which are used to elucidate my points, it is only fair that the writer bring to you a more or less intimate knowledge of what he considers the symptoms of the onset of the disease and also to acquaint you with his own estimate of the particular value of each. The three cardinal symptoms of chill, pain in the side, and rusty or red sputum which occur in the adult, may all be absent in children. Therefore, the early diagnosis of the disease in childhood must be made from an intimate knowledge of the first symptoms, an appreciation of their individual values, and repeated and frequent examinations of the chest.

The onset is almost always accompanied by vomiting and this vomiting has been said to take the place of a rigor, but of this I am doubtful for in practically every instance in which vomiting has occurred it has also been accompanied by some condition which approximated a chill, as coldness of the extremities and cyanosis which is most marked about the lips. That these latter are not directly connected with the vomiting is shown by their persistance even after that act is completed. In older children, the cause of vomiting is often traceable to an error in diet at the onset of an elevation of the temperature and therefore such a type of vomiting would have no direct connection with the disease in question. This uncertainty should be settled at once and in this the character of the vomitus will aid us; first, by the detection of undigested or indigestible articles of food; and secondly, by the time at which the vomitus was expelled in relation to the last meal. This gives a clue as to the efficiency of digestion.

A somewhat common feature of the onset is drowsiness which does not last for more than twenty-four hours and then disappears entirely or is replaced by a mild delirium. In children this delirium is easily overlooked as it often does not declare itself clearly but may only be evidenced by the vacancy of expression and an unnatural and restless attitude. Even when delirium is present the eye remains clear and bright.

Cough during the first forty-eight hours is a rather insignificant symptom and we do not attach much importance to its presence or absence during this period. Expectoration is only seen frequently in children when they have reached the age of ten or over; in those younger its occurrence is rare and under the age of four years is practically never encountered. However, occasionally blood may be early detected in mucus which has been swallowed and then ejected from the stomach by vomiting.

Headache and diffuse muscular pain are fairly constant if the child be one that is old enough to locate pain of this character intelligently. The characteristic pain, however, is pleuritic and may be referred to regions outside of the chest. In young children such pain is referred to the loin, the epigastrium, or to any situation to which the intercostal nerves are distributed. However, the characteristic of this pain is, that it is never definitely located by the child. Thus if in a very young child, we observed the evidences of abdominal pain with vomiting, the probability of pneumonia should be thought of, for at this period of life gastric disturbances are rarely accompanied by *early* abdominal pain.

Prostration is early and characteristic; the child

*Read before the Pediatric Section of the Medical Society of the County of Kings, February 23, 1910.

is visibly ill. This is out of all proportion to the symptoms present. Paleness of the face, which is apt to exist during the first few hours despite the fever, soon gives way to unilateral flushing of the cheeks, but this flushing is in no way indicative of the site of the disease. We have frequently demonstrated that it depends largely upon the posture of the child, the more dependent cheek being the one affected.

The respiration is always accelerated and has a jerky character often. There may be expiratory moan which when present is very distinctive. This moan is not very evident during rest but is exaggerated by crying or speaking. The pulse is at the onset full, strong, and frequent.

But it is the ratio between pulse and respiration which is of prime importance. The writer has never felt that much dependence could be placed upon increased respiration alone, but that to be of diagnostic value there must occur a marked increase and a disturbance of the ratio between pulse and respiration.

Thus if the normal ratio of approximately 1 to 4 was so disturbed that it was nearly 1 to 2 and the child exhibited other constitutional symptoms of the disease with or without definite physical signs in the chest, the diagnosis of lobar pneumonia can be presumably made.

A blood examination is not always feasible and as F. C. Wood says,* "As an aid to the diagnosis, blood cultures are of comparatively slight value except in the penumonias of old people where the physical signs are obscure and the pneumococcus frequently invades the blood in considerable numbers. A frank case of pneumonia can be diagnosed much more quickly and certainly from the physical signs than from a blood culture." However, as there is always present a polynuclear leukocytosis (except in grave cases) the rise of which occurs with the chill, this would have a distinct diagnostic, as well as prognostic value.

Since Sternberg demonstrated pneumococcus in his own saliva in health, many others have done the same. Netter took several hundreds in rotation and demonstrated it in over 20 per cent. of healthy persons. The New York commission's per cent. even exceeded this and their investigators show from 46 per cent. to 85 per cent. Buerger's study showed similar percentages but also demonstrated that the percentage was much higher in children than in adults. This renders the examination of the sputum an unnecessary as well as a useless measure.

In a consideration of the physical signs of the onset, we must be mindful of the occasional irregularity of the disease, an irregularity which while not confined to childhood seems to be much more common to that period. The following case will serve to illustrate this point:

Harriette M., age 12, was stricken with pneumonia on February 6, 1910, five days after the onset of the disease in her brother, aged 6. The disease ran a typical course until February 10, when the signs of commencing resolution were marked. The temperature remained high, however (never lower than 103° F., nor higher than 104° F.), and the mild delirium which was an early feature of the disease continued. The blood was taken for examination the following day and a Widal done by the Department of Health proved negative. On the 12th the signs of resolution were more marked, but temperature and delirium remained as before. On the 14th the temperature dropped in ten hours from 103.2° F. to 96.4° F. and a few hours later all evidences of the delirium had disappeared. From this time the girl made an uneventful recovery. Here, then, was an instance in which the stage of resolution was evidenced four days before the occurrence of the crisis. (This case will be reported at length at another time.)

*"Chemical and Microscopical Diagnosis;" Wood.

The earliest percussion signs which we look for are those which are due to congestion. As a consequence of this less air gets into the affected area and more is forced into the other portions of the lung, so that there is diminished resonance over the affected portion and exaggerated resonance elsewhere. The absence of this sign, however, is not evidence that pneumonia does not exist for percussion may fail to outline the affected area, either because it is limited in its extent, is covered by healthy lung, is deep seated, is masked by a gas distended stomach or intestine, or is situated in some part inaccessible to examination, as in the apex where covered by the shoulder and along the posterior border at the vertebra.

The earliest auscultatory signs are a feeble respiratory murmur over the affected portion, with rather high pitch, while the healthy portions of lung show exaggerated sounds. In addition to this there may be crepitant râles which are somewhat strictly localized to a small area. These are hard to find because of their temporary disappearance after the act of coughing and therefore the search for them involves diligence and patience and when found they are the strongest auscultatory evidence of lobar pneumonia.

Briefly, then, the symptomatology which the writer considers as absolutely essential to the diagnosis of the disease during the first twenty-four hours is: 1. A sudden onset, with immediate and sustained high temperature and a dry, hot skin. 2. Early prostration to the extent that the child will give up and show the visible signs of his illness. 3. Markedly increased respirations, with a decided disturbance of the ratio between pulse and respirations. 4. The exclusion of all other possible causes for the symptoms. Aside from these, however, there are symptoms which are corroborative, as: 1. Definite physical signs in the chest. 2. Initial vomiting. 3. Chill or something which approximates it. 4. Primary paleness of the face, with subsequent unilateral flushing. Of still less value, but still of some import, are the character of the pulse, cough, and possible expectoration. It is all right to theorize about the early symptomatology of this disease and to place our estimate upon the values of certain individual and associated symptoms, but the main question is, "Does it work?"

The following histories are submitted to your consideration:

Case I.—Girl, age 11. Attacked Monday noon. History of onset: Sudden attack of vomiting, not repeated, but accompanied by high temperature and marked headache; no chill, but chilly sensations. Examination at 2:30, T., 106°; P., 124; R., 68. Skin dry and hot, tongue slightly coated in center. Percussion at 7:30 showed nothing abnormal; auscultation, feeble respiratory murmur over most of the right lower lobe, increased murmur over other parts of chest. Diagnosis of pneumonia made at this time. Course, typical with crisis on seventh day.

Case II.—Girl, age 4. Attacked Monday at 5 P.M. History of onset: Repeated vomiting for half

hour, with high fever and slight cough. Examination at 8 P.M., T., 104.5°; P., 140; R., 59. Skin dry and hot and tongue much coated except at margins and tip. Percussion, very slight dullness over a small portion of the left upper lobe. Auscultation, feeble respiratory murmur, and a few very fine râles over large portion of same lobe; murmur intensified elsewhere over lung. Diagnosis made at this time. Three hours later, all physical signs more marked and with increase in respirations to 68; pulse and temperature remaining as before. Course, typical with crisis on sixth day and followed by empyema.

CASE III.—Boy of 6. Attacked Sunday at 7 P.M. History of onset: Tried to vomit and only succeeded in bringing up small amount, but had high fever and what seemed like a chill; cried to be put to bed. Examination at 8 P.M., T., 104°; P., 134; R., 62. Physical examination revealed no signs in chest. Face quite pale. Diagnosis of pneumonia made on symptoms present and by exclusion. Four hours later the condition remained practically the same. Seven hours later (twelve hours after the onset) examination showed feeble respiratory murmur over a small part of left lower lobe; percussion negative. Course, typical with crisis on eighth day, on ninth day sudden rise to 105, with final crisis fourteen hours later.

CASE IV.—Boy, age 2 years. Attacked Saturday at noon. History of onset: Slight convulsion, followed by vomiting and diarrhea and accompanied by high temperature. Examination at 3 P.M., T., 105.2°; P., 160; R., 73. Some very fine râles localized at one point near right apex; no other signs. Diagnosis made at this time of pneumonia. Nine P.M., respiratory murmur much weakened over most of the right apex and slight dullness over about an inch area. Next day, diarrhea had entirely disappeared without treatment (diet restricted, of course); physical signs in chest much more marked. Course, typical with crisis on sixth day.

CASE V.—Boy, age 6. Attacked Monday at 9 P.M. History of onset: Sudden attack of vomiting, accompanied by high temperature and preceded by chilliness and some headache. Severe pain in the right side of the abdomen, apparently crampy in character. Examination at 11 P.M. (having been called by the attending physician to confirm his diagnosis of appendicitis), T., 104°; P., 137; R., 63. Tongue slightly coated in center. Percussion, small area of scarcely appreciable dullness over middle right lobe. Auscultation, enfeebled respiratory murmur over most of the lobe and very fine râles localized to small area near center of the lobe. Diagnosis made of lobar pneumonia; appendicitis excluded. Attending physician preferred to withhold diagnosis for a time. Twelve hours later, signs in chest unchanged, T. P. and R. same. Pain in abdomen less severe. Unilateral flushing of check. Course (after first two days) typical with crisis on seventh day.

CASE VI.—Boy, age 3. Attacked Thursday at 5 P.M. History of onset: Vomiting and diarrhea with high temperature, chilliness, and very pale face; lips bluish. Had been to afternoon party and eaten freely of cakes and candies. These were in the vomitus. Examination at 9 P.M., T., 105°; P., 122; R., 57. Tongue coated in center; abdomen tympanitic. Percussion revealed nothing; auscultation, feeble respiratory murmur doubtful over small area of lower right lobe. Diagnosis of pneumonia made at this time. Next morning at 8, no detectable signs on percussion or auscultation. T., 104; P., 134; R., 61. Tongue much more coated, diarrhea stopped, abdomen flat. Same day at noon, percussion showed small area of dullness over center of lower right lobe; auscultation, much enfeebled respiratory murmur over whole lobe and intensified murmur elsewhere. Course, typical with crisis on seventh day.

The writer has purposely avoided elaborating upon these histories, for to conserve the purpose of this paper, it is only necessary to mention the few salient points which have a direct bearing upon the question. And for our purpose, the submission of six recent reports is as serviceable as the histories of sixty.

It is perfectly logical to assume that if by certain symptoms and their association with one another, the clinician is able to diagnose a disease and to predict its probable course and such diagnosis and prediction is confirmed by the typical course of the disease in later days, that by a similar process of reasoning and deduction under similar circumstances he should be able to diagnose the disease even though his prediction that it will follow the usual course be upset by an unusual course of the disease. The essential thing is not that the prediction of a typical course be borne out in all instances, but that the typical course follow such a large proportion of such predictions that it indicates that the scheme of early diagnosis is the right one and that it is possible to diagnose the disease in question by such means. In other words, if it is possible to diagnose lobar pneumonia upon the first day of the disease and have all doubt as to error dissipated by the subsequent typical course of stages of congestion, hepatization, and resolution, it is possible by the same signs to diagnose pneumonia, even if the disease be arrested some time during the first stage.

Enough of the former cases have been submitted to show that such an early diagnosis of this disease is feasible. It remains now to submit to you, the following histories of instances in which by similar methods a positive diagnoss was made, although the disease later exhibited the unusual course.

Because of the lack of time, I feel that we can fairly pass over the consideration of the seventy-two-hours types of the disease, for in these short duration pneumonias there is little if any difference from the ordinary type, except in the length of their course. The physical signs are as well marked as are those of any mild pneumonia, and they clearly indicate that the disease is passing through the usual stages, although the length of each stage is much shortened. And then again, if we are convinced from our clinical studies of the disease that a much shorter duration may exist and that the disease may end within forty-eight or twenty-four hours without having gone through all of the usual stages, it is not necessary to elaborate upon the longer-coursed disease.

CASE I.—Boy, age 7. Attacked Monday noon. History of onset: Severe vomiting attack with high temperature and slight cough. In the vomitus there was blood-streaked mucus. A slight chill had occurred with the vomiting. Examination at 2 P.M., T., 104°; P., 142; R., 61. Skin dry and hot; tongue much coated except at margins and tip. Percussion, very slight dullness over part of right lower lobe. Auscultation, feeble respiratory murmur over larger part of same lobe, but intensified elsewhere. Diagnosis made of pneumonia. Six P.M., T., P. and R.

practically the same; signs in lung more marked. Ten P.M., no apparent change in the conditions, except tongue is cleaner. Next morning at 7, no change, except that signs seem slightly more marked. One P.M., T., 103; P., 136; R., 49, marked improvement in signs in chest. Five P.M., no dullness, auscultation shows very slightly enfeebled respiratory murmur; T., 101°; P., 121; R., 32. Nine P.M., T., 98°; P., 86; R., 23; no signs detectable in chest, cough persists. Course, nothing further abnormal, except cough for two days.

Case II.—Boy, age 10. Attacked Thursday at 7 P.M. History of onset: Chilliness and headache preceded a sudden attack of vomiting with high temperature. Examination at 10 P.M., T., 104°; P., 135; R., 60. Tongue slightly coated, Percussion, a hardly detectable dullness over a portion of the left lower lobe with auscultation showing slightly enfeebled respiratory murmur over a considerable portion of that lobe and crepitant râles localized at one small area. Diagnosis made at this visit. Examination at 7 next morning, T., 103.2°; P., 140; R., 56. Percussion signs the same; auscultation signs much more marked, but apparently over a somewhat smaller area. Two P.M., T., 100°; P., 116; R., 36. Dullness entirely disappeared, respiratory murmur almost normal over whole of chest. Five P.M., no physical signs apparent in chest, except a few fine râles localized over small area of left lower lobe; T., 99°; P., 110; R., 35. Ten P.M., T., 98°; P., 86; R., 22. Course normal, except for localized râles which persisted for thirty-six hours.

Case III.—Girl, age 9. Attacked Tuesday 4 P.M. History of onset: Sudden attack of vomiting, not repeated, but accompanied by considerable headache and high temperature and chilly sensations. Examination at 7 P.M., T., 105.2°; P., 130; R., 62; skin dry and hot, face pale, tongue slightly coated. Percussion, nothing abnormal. Auscultation, feeble respiratory murmur over small part of right lower lobe, intensified elsewhere. Diagnosis, pneumonia. Examination at midnight, T., P. and R. practically the same. Auscultation signs slightly more marked and very slight percussion dullness over same area. Localized crepitant râles quite evident. Examination at 9 A.M. (next day), T., P. and R., no marked change. Signs in chest practically as before. At noon, at 6 P.M., and at 11 P.M. there was no appreciable change in the conditions. Thursday at 8 A.M., dullness seemed to have become more restricted in area, auscultation the same. T., 104°; P., 142; R., 56. At noon, child had profuse sweating and examination at 2 P.M. showed T., 97.2° P., 140; R., 27. Abundant râles over about one-half of the area of the right lower lobe. Course, normal, except for rather free expectoration for two days. Pneumococcus present.

Case IV.—Boy, age 2½ years. Attacked Sunday at 3 P.M. History of onset: Vomiting and diarrhea with high temperature, chilliness, and bluish lips. Considerable pain apparently in ear. Examination at 7 P.M., T., 106°; P., 134; R., 66. Tongue coated in center, abdomen distended with gas. Percussion, negative. Auscultation, feeble respiratory murmur over very small area of lower left lobe. Diagnosis of pneumonia. Eleven P.M., all physical signs much more marked; T., P. and R. about the same. Seven A.M. Monday, no change, except that dullness is more marked. Noon, 8 P.M. Monday, and 8 A.M., noon and 4 P.M. Tuesday, conditions without practical change. Tuesday 11 P.M., T., 104°; P., 124; R., 48, but without changes in chest. Wednesday 6 A.M., T., 100.2°; P., 132; R., 34. Wednesday noon, T., 99°; P., 110; R., 26, but still no change in chest. Course, Wednesday 6 P.M., T., P. and R. normal and appreciable improvement in signs in chest. From this time everything was normal, except that râles persisted over part of affected area for three days, progressively becoming less and less marked.

Case V.—Girl, age 9 years. Attacked Saturday at 5 P.M. History of onset: Slight headache preceding a sudden attack of vomiting and high temperature and quickly followed by stitchy pain in the right side of chest. Examination at 10 P.M., T., 103°; P., 122; R., 57. Tongue clean. Percussion and auscultation revealed nothing, although the respirations were jerky in character. Diagnosis was deferred until later, but a presumptive diagnosis of pneumonia was made. Eight A.M. Sunday, T., 104.3°; P., 136; R., 63, but no appreciable signs in the chest. One P.M., no change. Diagnosis positively made at this time. Nine P.M., T., 103°; P., 124; R., 61. Feeble respiratory murmur over large part of right middle lobe and very slight dullness still more limited over same area. Seven A.M. Monday, pain in side entirely gone. Dullness disappearing, auscultatory signs more in one small portion of lobe, but still evident over most of lobe. T., 101°; P., 112; R., 48. Three P.M., T., normal; P., 106; R., 31. Fine râles somewhat indistinctly heard over affected area Course, T., P. and R. normal at 9 P.M. and followed by expectoration of rusty sputum for about fourteen hours and scanty expectoration and slight cough for one day.

Case VI.—Boy, age 11. Attacked Thursday at 9 P.M. History of onset: Decided chill following slight headache which persisted for about six hours. Sudden attack of vomiting, violent for about fifteen minutes then subsiding. High temperature and flushed cheeks. Ten P.M. examination, T., 104.2°; P., 134; R., 58. Respirations were jerky and accompanied with decided expiratory moan. Diagnosis pneumonia. Seven A.M. Friday, T., 105°; P., 146; R., 56. No signs in chest, but child very ill. Flushing unilateral on cheeks. Skin very hot and dry. Mild delirium. Friday noon, no change in condition. Six P.M., T., P. and R. remained practically the same and thorough search did not reveal any signs in chest. All other possibilities excluded. Blood examination showed polynuclear leukocytosis. Eleven P.M., no appreciable change. Saturday morning at 7, T., 97.3°; P., 108; R., 24. Course, normal from this hour on.

My own interest in this question is great, so great that one year from now I shall seek to bring before you a further study of this problem. In this I invite the cooperation of every one present, and any clinical reports which are brought to my attention will receive the fullest recognition.

42 Gates Avenue.

CONCEPTUAL FACTORS IN VERTIGO AND NYSTAGMUS:

A STUDY OF BALANCE REACTIONS.

By PERCY FRIDENBERG, M.D.,

NEW YORK,

JUNIOR SURGEON, NEW YORK EYE AND EAR INFIRMARY.

Intellectual concepts and judgment play an important rôle in equilibrium, as might be expected from the fact that balance is an adjustment of the entire organism to criteria of ideal space and direction, and that in the interests of a maximum factor

of safety for the organism, this adjustment is mediated by a number of sensory organs acting in association. Thus, concepts of vision, eye position and innervation, tactile and muscle sense, static and dynamic stimulation from the labyrinth, unite to produce a composite but uniform impression, which is referred by the sensorium to the memory-pictures, the "local signs," of similar previous impression complexes. The modification or even complete suppression of one of these components would not inevitably and necessarily disturb balance or cause the illusion of disequilibrium and motion which we call dizziness. Thus blindness, astereognosis, or destruction of the labyrinth, alone may be compatible with fairly good balance and subjective well being. A discrepancy or incongruity, however slight in the total impression, may be prevented by subconscious and vicarious adjustment on the part of the unaffected component. On the other hand, a slight disturbance or modification of a single sensory factor might be followed by marked disequilibrium and violent motor reactions, in case the conditions were such as to interfere with the correcting factor usually supplied by other organs. This is a matter of great practical and clinical, as well as theoretical, importance. That there are such conditions, in heath and disease, can, I think, be shown, and the conception of vertigo and nystagmus as balance-confusion and balance-correction respectively, seems to be in accordance with the data to be adduced. The fact, demonstrated by Nagel, that there is a whole series of dizziness forms, ranging from one extreme of purely visual confusion to the opposite of mechanical rotational disturbance, would indicate that vertigo is not a simple sensation. Again, as our ideas of balance and position are demonstrably dependent on judgment of sensory impression-complexes, it is natural to assume that confusion of these impressions cannot be a simple sensory reaction.

A single instance from the physiology of vision may be instructive in this connection. Verticality in external objects is judged largely by correspondance with the vertical meridian of the cornea and retina, which adjusts itself automatically, by torsion movements, to compensate for and correct minimal inclination due to alterations of head position which are too slight to be noticed subjectively. This correction is unconscious and automatic, and is replaced, for high degrees, by the gravity reaction of the static labyrinth, which is connected with a very definite conception of altered verticality. Now, we are all familiar with the apparent alteration of verticality in objects situated along the banked curve of a railroad when seen from a car window; an illusion which has been very widely experienced, carefully studied, and explained without contradiction as due to the actual inclination of the observer and not, as was incorrectly supposed, due to a combination of centrifugal force and gravity with a resultant pull on the static terminals. This inclination of the observer's own body and head is obscured by the simultaneous impressions of translational and rotational movement in rounding the curve. As soon as we become conscious, by any means, of the actual alteration of position in our own body, the illusion disappears, although the labyrinthine stimulation, with the actual position change which induced it, evidently persists. It suffices merely to look well out of the car window to see the trees and telegraph pole resume their normal verticality, and v. Cyon has shown that it is the inclination of the window frames, doors, and floor of the car which misleads us and causes us to overlook our own actual tilt. As soon as these visual factors of position-judgment are corrected, we recognize our own defection and deflection, and cease to attribute them to objects in the outer world. An interesting corollary of this observation is the fact that actual inclination of marked degree in rounding curves in such exercises as skating, bicycling, riding, is never attended with illusions of tilt in external objects. This is logically explainted according to our view, by the fact that we are actively conscious of the inclination of our own body, the more so as it is mainly or exclusively the result of our own conscious and intended effort to maintain the upright position and keep up speed in turning in opposition to centrifugal force, and not, as in the railway car, a passive alteration. A comparison of these sensations with those observed on inclined railways shows that similar errors in judgment of verticality occur, and these, too, disappear spontaneously as soon as we become aware of the actual inclination of our own body. Where there is no subjective inclination at all, as in gravity railways whose cars have banked seats, there is illusion of tilt. Numerous observations all admitting of the same interpretation, might be cited from every day life and well known laboratory data, but enough has been adduced, I think, to show quite clearly that judgment of verticality is neither a visual nor a labyrinthine sensation but a judgment reaction to these, and possibly other factors.

An example from clinical otology will now show that labyrinthine dizziness and its reactions are the direct analogues in pathology, and that they too can be reasonably explained only as judgment-disturbances or confusion and a compensation of disequilibrium. We know that irritative lesions of the labyrinth, and especially those in Ménière's disease are attended by extreme vertigo and intense violent nystagmus. Post-mortem examination has shown and the pathogenesis of this affection would indicate that the actual extent of histological change, of hemorrhagic effusion, and of resulting compressive irritation of the ampullæ is by no means marked. Why are the sensory disturbance and motor reaction so extreme when compared with the corresponding sequelæ of rotational stimulation? We know that the most extreme stimulation of the canals in whirling, waltzing, somersaults, and other gymnastic feats, does not necessarily lead to vertigo. Is it not logical to infer, comparing these reactions with those of vertigo ab aure læsa, labyrinthine apoplexy, that in the latter case the absence of the usual visual, tactile and fixational components of actual rotation and the consequent absence of correcting sensations and judgments intensifies the confusion? We might put it thus paradoxically that in one case the patient is dizzy because he knows he is not moving, and feels that he is, and in the other case is not dizzy because he knows he ought to be dizzy from the motion which he intended and distinctly senses.

These observations may also be applied to the much-discussed relationship of dizziness and nystagmus, and show, I think, quite clearly that the confusion is not directly caused by the motor reaction. There is nystagmus without dizziness, as in looking out of a car window or carrousel, and dizziness without nystagmas, as in looking at objects reflected in an

unsteady mirror, causing double images by means of prisms, and so on. These examples again corroborate what we have noted above. So long as the sensations of disturbed vision or of ocular motion (as in correcting the diplopia) are correctly attributed to their causes in the external world and in subjective effort, respectively, there is no confusion and no dizziness. Where this subconscious explanation is lacking, dizziness immediately ensues. This, it is worth noting, usually takes place with very slight alterations, very weak prisms which cause an almost imperceptible diplopia, and so on. As before, we might say, we know we are seeing double and are not confused, or are aware of a muscular effort which results in correction of the double vision and for the same reason, again, understand the reaction and are guarded against confusion. It is interesting that when more than one sensational component is concerned, very slight degrees of discrepancy will cause illusions of disequilibrium and are immediately followed by marked dizziness. This can be observed most beautifully in the vertigo and nausea caused by looking at the image of an object which is mirrored in a trembling glass or a swinging pane. The conceptual element, however, is not lacking even in this instance. Small amounts of trembling or displacement which escape ordinary observation immediately, and according to our theory naturally, cause dizziness. As soon as the oscillations of the mirror are gross enough to be seen and understood we realize, one might almost say, expect, that our visual impressions will be irregular. We are prepared for and allow for the sensory disturbance and judgment of subjective position is not confused. There is no dizziness unless, on the other hand, the motions of the reflecting surface become so violent and irregular that the mind can not cope with them on any basis of past experience and habit-memory. Personal experience has convinced me that the same conceptual factors are active even in so apparently mechanical a form of dizziness as that connected with sea sickness. The difference of susceptibility in individuals would indicate this. Again, it is striking that nausea comes on more easily below decks, where there is less visual evidence of the vessel's motion. This is usually attributed to deficient ventilation, the varied smells of ship board, and so on, but as these factors are almost entirely eliminated in certain cases, particularly in sailing vessels, where the same variation is noted, they must play a subordinate rôle. Voluntary concentration of attention and strong emotional stimuli also inhibit nausea. I know of numbers of individuals who do not suffer during stormy, windy, rough weather and succumb when the tempest subsides and the ship rolls lazily. I have seen a fishing party get sick when a calm came on and the fish stopped biting.

The conceptual element in sensations of disequilibrium is paralleled closely by similar factors in the various motor reactions which have been variously explained as purely reflexed, or as compensatory and corrective. This is particularly striking in the most uniform and typical reaction of nystagmus. The analogy can be understood more thoroughly if we preface an analysis of this phenomenon with a consideration of the visual and fixational concepts in normal balance. It is beyond doubt that the conception of our relations to verticality and ideal space depend largely on ocular impressions, not only retinal space and position, data of a purely visual character, but innervation states, sensation of eye balance, and of position, all of which are eventually connected with local signs acquired in the course of time by the habitual exercise of ocular fixation. The fixational element of balance and of control and judgment of this function is so traditional, although largely subconscious and automatic, that it becomes an integral part of the entire function and is exercised in the absence of all visual impressions and appears as a reflex of purely labyrinthine stimulation. The conceptual feature in balance relates to regular progression of objects in the outer world across the field of fixation and vision, a form of motion which corresponds to rotation of space and also to subjective rotation. The form of fixation observed under physiological conditions is that of a clonic spasm of the associated muscles for lateral rotation of the globe. The resulting motion of the eye-ball is composed of a rapid fixation leap in the direction of the approaching object, and a slow motion in the opposite direction, as if the eye were carried along by the object it fixes. In marked contrast to non-equilibrational forms of nystagmus, of which clinical ophthalmology recognizes a number, this form is not an oscillation about a central point of rest with equally rapid and extensive motions to either side. Fixational nystagmus could be represented graphically by a curve which reaches but never passes to the opposite side of a base line. This curve would show waves of equal length, but very unequal rising and descending limbs. The first portion of each wave would be short and almost vertical, the descending second portion long and gradual, the whole suggesting the pulse wave. The ascending limb, representing the rapid aiming or correction leap ("Einstellung" of the Germans) indicates the direction of fixational nystagmus which is identical, as all observers agree, with labyrinthine and cerebellar nystagmus. The purpose of this physiological fixation clonus is the retention of clear vision of objects in regular motion. It is to be noted that we have no knowledge of the motion of the eyeball during this reaction, and cannot see it even if we look into a mirror while studying the phenomenon. The sensation of eye motion is externalized in accordance with habit and memory, and rises into consciousness as subjective motion only when the reaction is markedly abnormal and hence incongruous with previous psychical experience. At such times even slight ocular motion may produce marked discomfort and induce vertigo, as in overcoming a prism held in front of the eye. The factor of diplopia can easily be excluded, and it is rather significant that, in ocular palsies, widely separated double images do not cause dizziness, but this comes on when the images are so close together as to be fused with an effort, or to remain partially separated and cause visual confusion. The vertigo in miners' nystagmus is similarly explained most rationally by unusual and prolonged muscle strain in the effort to fix, under abnormal conditions of eye-position and of illumination.

The recognition of the purposive character of labyrinthine nystagmus and of the conceptual elements in its function is facilitated by our knowledge of a specific character in the mode of irritation and in the centripetal stimulus originating in each semicircular canal. Stated broadly, the stimulation of a given canal or associated set corresponds with the stimulation physiologically afforded by actual rotation of the subject in the plane of the canal in question. Thus, rotation to the right causes irritation

in the ampullar terminals of the right external horizontal canal, is accompanied by a sensation of subjective motion to the right, often to the point of illusion of loss of balance, and is followed by a series of motor reactions all of which have as their object a compensation for the actual or sensed change in position or direction. Increased tonus of the muscles of the extremities and trunk on the right side tends to counteract the actual or apparent loss of balance; innervation of these muscles tends to restore equilibrium and to regain the original position, as it is only by extension of limbs and trunk on the right side that we can move to the left. The apparent discrepancy in the head motion, which turns to the left, is explained away, at once, if we consider that correction of the head position is accomplished by the lateral rotators of the head to the left. The oculomotor reaction, consisting of fixation clonus toward the irritated ampulla, *i. e.*, toward the direction of actual or sensed subjective motion, which is also the direction from which objects in the external world appear to be moving, has the same correcting purpose, if we now bear in mind the importance of the visual or optical impressions acquired under physiological conditions, that were noted above. The muscles concerned in this ocular reaction are the associated lateral rotators (homonymous adductor and crossed adductor) which again, like all of the muscles mentioned, are under control of the cerebellar centres of the irritated side. Incidentally, this evidently purposive character of nystagmus, as well as its regularity and uniformity, tend to disprove the widely accepted theory of Purkinje that nystagmus is the cause of dizziness. Considering the well-known irregularity of action in the various muscles and the striking lack of power in the entire system in any marked condition of vertigo, the ocular reaction would, on this hypothesis, form a striking and inexplicable exception and anomaly. The interpretation of vertigo as an illusion, as an incoordination of sensory impressions of balance and direction, and of nystagmus as a purposeful reaction for the correction of this disturbance by fixational support, in accordance with definite local signs of previous ocular motion, will, I think, simplify a study of the entire subject of labyrinthine reactions, and facilitate the logical interpretation of the varied data which clinical neurology and otology are gathering on a basis of definite functional tests of the non-acoustic labyrinth and of its static and dynamic components.

60 East Fifty-eighth Street.

A CASE OF HIP-JOINT DISEASE.

By JOHN A. WYETH, M.D., LL.D.,

NEW YORK.

PROFESSOR OF SURGERY, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

I report the following case for the reason that it shows a perfect restoration of function after a well-marked attack of morbus coxarius which required careful and persistent treatment for nearly three years.

Noel P. H., the only child of parents, both of whom were in good physical condition, was born December 25, 1894. At three years of age he had a severe attack of diphtheria which left him partially paralyzed for about a year. All symptoms of paralysis disappeared at the end of twelve months, after which time the child walked well and seemed to be in perfect health.

At the age of six he fell from a balcony about 12 feet high, striking upon his head and shoulders. He suffered no marked inconvenience from this accident, and in three or four days was as lively upon his feet as ever. Six weeks later the mother first noticed a slight hitch in his gait, which soon developed into a decided limp. She also observed about this time that in standing he began to favor the left leg, and to complain of pain in the left hip and knee when walking.

When I examined him, there were all the evidences of beginning hip-joint disease. The gluteal fold of the left side was less accentuated than on the right. Upon placing the child flat on his back on a hard table, while the right leg could be brought down until the popliteal space touched the table

without any elevation of the spine, when this was done with the opposite member the spinal column was immediately raised. As pointed out by Professor Lewis A. Sayre, this is one of the most important symptoms of hip-joint involvement.

A long Sayre extension hip splint was applied at once, and was worn night and day practically without interruption for three years. The child soon became accustomed to it, and did not seem to be inconvenienced by sleeping in the instrument. By constant care and watchfulness on the part of his mother, no sores were developed, and the treatment was thoroughly carried out. At the end of three years the instrument was discontinued.

The patient is now fourteen years of age, and on May 1, 1909, won the second prize of a Junior Marathon race, a distance of five miles, run in a

driving rainstorm over a rough country road, the boy's time being 32½ minutes. The professional record for that distance, I am told, is 24 minutes. As there were twenty contestants, several of whom were from three to five years older than this patient, the record of endurance is the more remarkable.

DUODENAL ULCER WITH PERFORATION ACCOMPANIED BY CHRONIC APPENDICITIS.

OPERATION TWELVE HOURS AFTER PERFORATION OF DUODENUM FOR REMOVAL OF APPENDIX AND CLOSURE OF PERFORATION; RECOVERY.

By SURGEON H. W. AUSTIN, U.S.P.H. and M.H.S.

The noteworthy features in this case are the complication of diseases making early diagnosis difficult, and the favorable result of an operation twelve hours after perforation of the duodenum.

W. B. T., aged 25 years, nativity New York, oiler on Steamer *Relief*, was admitted to the United State Marine Hospital, New York, September 20, 1909, with the provisional diagnosis of acute gastritis and probably ulcer of the stomach. The following notes are taken from the clinical record of the case.

Family history: Mother died of consumption of throat. Father died of dropsy. Has had the usual diseases of childhood, measles, mumps, whooping-cough, and chicken-pox. Since adult life he has enjoyed good health, with the exception of occasional attacks of stomach trouble for the past seven years. Has had three attacks of gonorrhea, one very recently from which he is not entirely recovered. Never had syphilis.

Day of admission: Patient complains of pain in stomach and nausea. Has to produce vomiting after meals to get relief. Pain comes one hour after meals. No blood in vomited matter. Bowels usually constipated. Tongue coated. Breath foul.

Physical examination: Temperature normal. Heart and lungs negative. Rigidity of abdominal muscles. Marked tenderness over epigastrium. Palpation negative except showing tenderness in epigastric region. Body poorly nourished.

Analysis of stomach contents: Total acidity, 75; combined HCl, .005475 per cent.; free HCl, .021 per cent.; mucus and bile, but no blood.

The attacks of stomach trouble would last about a week and recur at intervals of six weeks, for which no cause could be ascertained. Patient states that these attacks come on at such regular intervals he can know the day they will occur. The present attack is more severe than the previous ones. Has no eructation of gas, but pyrosis, vomiting, and great distress in the stomach, particularly about one hour after midday meal. Stomach washed with solution of soda bicarbonate gave some relief. Rice water diet prescribed, this being rejected rectal alimentation was resorted to. This, with daily washing of the stomach with a mild alkaline solution of soda bicarbonate, constituted the treatment for several days. The patient's condition somewhat improved for several days. It was noticed, however, that there was considerable tenderness on pressure over McBurney's point and occasional pain in this region, but there was free evacuation of the bowels and no rise in the patient's temperature. On the evening of September 28 the patient was seized with acute pain in the abdomen. The pain was so severe that the patient fell back in bed with a cry. The attention of the medical officer in charge of the ward was called to the case about an hour later. Tenderness over the abdomen, especially at McBurney's point and over the epigastric region was marked, and the pulse was becoming more rapid and the respirations more frequent. Morphine to relieve pain was ordered and a close watch of symptoms directed. The patient had a comfortable night.

September 29: This morning the patient is suffering considerable pain in the abdomen and there is again general rigidity of abdominal muscles with tympanitis. Pulse rate increased (96). Temperature normal. It was evident that the patient had a general peritonitis, and it was decided to operate at once.

The patient having been prepared a median incision about four inches in length was made extending to a little below the umbilicus. The intestines protruding through the wound were congested to a dark red and covered with lymph. A cloudy serous fluid was found in the abdomen and a fecal odor observed. The appendix was searched for and found closely adherent to the cecum its entire length. The mouth of the appendix was firmly blocked by a hard fecal mass about the size of an English walnut which was with much difficulty dislodged. The appendix was inflamed, but not perforated. I performed an appendectomy, which owing to the many adhesions due to an earlier inflammation, was tedious. I then examined the stomach for perforation or for ulcers and found nothing abnormal. Next I examined the duodenum and in manipulating, the gas from the bowels could be heard distinctly passing through the perforation. There was found a perforation in the upper posterior wall of the second part of the duodenum. The ulcer was about the size of a penny and the perforation about the size of a lead pencil. The perforation was closed by Lembert sutures, the edges of the ulcer being well turned in.

I was preparing for a gastroenterostomy when the patient showed signs of so much shock (pulse 180) I concluded it would not be safe to prolong the operation. The abdomen was wiped out without flushing and closed with two rows of sutures, a drainage tube being inserted. The administration of strychnine and 600 c.c. of normal salt solution by hypodermoclysis was ordered and the patient put to bed in Fowler's position surrounded by hot water-bags. Normal salt solution by hypodermoclysis was again administered after the patient was in bed, which brought the pulse rate down to 140, and improved the volume. Patient reacted from the anesthetic rapidly and the pulse gradually became slower and stronger. Vomited a few times the evening of the day of operation, the vomitus being slightly streaked with blood. Strictly rectal feeding was ordered—peptonized milk given in doses of one-half pint. The patient made a rapid recovery. The wound was closed perfectly October 9.

Rectal feeding continued for one month and then the patient was allowed milk and other light diet per orem. He gained weight rapidly and was discharged in perfect health December 30.

He is now employed again upon his ship and when he called at the hospital February 4 he had grown so stout I hardly knew him.

Cases of this character are most encouraging, but the results I have had in perforation in typhoid cases are not so. However, I believe many of these cases will recover and shall continue to give them the chance.

ELECTRIC ANESTHESIA.*

By MARCUS M. JOHNSON, M.D.,

HARTFORD, CONN.

That electricity is at last no longer a theory but a practical realization for operative procedure on mankind was recently most conclusively proven by Dr. Lonise G. Robinovitch, of New York, editor of the *Journal of Mental Pathology*, and a skilled operator on the electrical methods of resuscitation of lower animals, before a large assemblage of Hartford's most prominent physicians and surgeons.

On the night of January 24, 1910, Dr. Robinovitch electrocuted a rabbit by her own electrical equipment before the Hartford Medical Society, and after permitting one of the physicians present to listen for the extinct heart beats of the animal, again restored the heart and vital organs to their normal functions by reversing the current, the animal promptly getting up and running about the hall. On the following day she demonstrated, for the first time in the annals of surgery, the uses of electricity for anesthetic purposes on man.

The operation was performed by Dr. Marcus M. Johnson, assisted by Dr. Edward Herr, at the St. Francis Hospital, upon a young Austrian patient, John C., age twenty-three years, who had entered a few days previously complaining of frozen feet. Subsequently gangrene ensued and amputation was agreed upon on four toes, including the two great ones. Dr. Robinovitch arranged her electrical device upon a long table in the operating room. From the storage batteries of an automobile stationed without, a wire was led through a window to the operating room and connected with a rheostat for governing the current, and two meters, one for voltage and the other for ampèrage. Finally, a small make and break switch was inserted in the circuit and the equipment on the long table was complete. The patient now blindfolded, but otherwise unrestrained, was brought in on the operating table and placed in a position alongside and parallel to the long table. The negative rheophore, a zinc electrode covered with moistened cotton, was placed over the sacral vertebræ; another roller hand cathode, moistened in saline solution, was placed over the site of the anterior crural nerve at its entrance into Scarpa's triangle. A third metallic cotton-covered electrode was bound down over the posterior tibial nerve just behind the internal malleolus, and a fourth similarly cotton-covered electrode was fixed over the anterior tibial nerve at a point just external to the crest of the tibia, and eight inches above the ankle joint. The latter two electrodes were anodes.

Immediately upon the making of the current anesthesia of the limb below the electrodes was complete and incision was promptly made. Apparently, no pain was experienced by the patient. Following the amputation of the great toe of the right foot, the electrodes were transferred to the left leg. Here the great, second, and third toes were amputated and flaps sutured over. During the operation, which was of forty-five minutes' duration, the patient laughed and conversed freely with Dr. Robinovitch and nearby surgeons, expressing himself as utterly unconscious to any sensation in the limb being operated upon, even when liberal incisions into the normal tissue were made for flaps and the bone was separated by bone forceps. Two hours following the operation patient was found sitting up in bed in an evident cheerful frame of mind.

The advantages of this method of anesthesia are obvious. Incision is allowable immediately on the closure of the circuit, thereby saving time for the operator. The frequent, and often times serious, after effects of ether were totally absent, *i.e.* vomiting, gastric distress, and more remote complications of ether pneumonia and nephritis were surmounted. In their places the patient showed little, if any, concern of having had an operation performed.

The type of current utilized by Dr. Robinovitch is the same as is used by her for purposes of resuscitation, whether it be coma from electrocution, opium, or other narcotics.

The current used is a direct current from storage batteries, capacity one hundred ampères each. The current is interrupted 6,000 to 7,000 times per minute, period of passage of the current being 1-10 of entire time. The current passes from the periphery centrally. The direct current was interrupted with Dr. Robinovitch's model of interrupter. The meters registered 54 volts and four milliampères of current coursing through the patient's body locally. Electrodes used: lumbar, 12×25 centimeters; roller electrode, 2x2; leg electrodes, each 4x8 cm.

*Report presented at the February meeting of the New York German Medical Society, held at the Academy of Medicine.

Sore Nipples.—Among the numerous remedies recommended for sore nipples the compound tincture of benzoin is probably one of the best, as a local application. —*The Southern Clinic.*

Considerations on the Technique of the Conservative Cesarean Section as Practised After the Old Method.—A. Couvelaire has performed fourteen cesarean sections and observed all the sections made at the Baudeloque since 1901, and on these bases his opinions on the technique of this operation. To secure hemastasis it is not necessary to throw around the uterus an elastic ligature; we may depend on the tonic muscular action of the uterus itself, fortified by a preventive dose of ergotin, given hypodermically just before the operation. In case of atony a careful hemostatic suture is important, which will coaptate the entire thickness of the uterus, and be solid enough to resist powerful uterine contractions. Hemostasis should be so perfect as to render abdominal drainage unnecessary, but uterovaginal drainage should be provided for. The inclined position and exteriorization of the uterus should be provided, for protection of the field of operation. Only a careful selection of cases will provide against autoinfection. The section leaves behind it a cicatrix, which is always a weak point. We cannot depend on its holding in a following labor. The conservative section demands in most cases prevention of repeated labor by sterilization.—*Annales de Gynécologie et d'Obstetrique.*

The Work Cure in Tuberculosis.—F. Dumarest contrasts the rest cure, so frequently used in tuberculosis, with the newer method of treatment used in England, which may be called the work cure. In some English sanatoria a system of graduated labor is made use of, originated by Paterson, which has been quite successful. In applying this system we think less of the physical signs than we do of the general condition of the patient. When a patient shows fever he is put to bed until this has passed away. After this he is given a small amount of labor equivalent to the lifting of a certain amount of weight. As he is able to do this it is gradually increased. The work is, as far as possible, performed in the open air, being for the men gardening, carpentering, painting, wood-cutting, etc. All these trades are carried on so as to be of value in the maintenance of the sanatorium. The women cultivate garden vegetables for the table, and care for poultry. The coming on of slight fever in such persons is considered a favorable sign rather than otherwise, and as indicating the formation of a power of resistance to the disease. It is a reaction such as occurs when tuberculin is injected. Under this system 80 per cent. of the patients are cured. Work is considered a part of the cure, and those who are not willing to perform it are not admitted to the sanatorium.—*Le Bulletin Médical.*

THE SEWAGE POLLUTION OF STREAMS.

THE now almost famous address delivered by Prof. W. T. Sedgwick of the Massachusetts Institute of Technology before the recent annual conference of the sanitary officers of the State of New York has, perhaps, effected its object, or at least partially effected its object. Certainly, the facts pointed to in the address have aroused the attention of those interested in sanitary matters not only in New York State but throughout the continent of North America and in Europe. Needless to say it is well that this should have been so, for if an abuse is to be removed, it must be constantly discussed in the journals, in order that public opinion may be properly aroused on the matter. There is little doubt that the privilege of sewage disposal is abused in this country, or rather that the laws regulating the disposal of sewage are in many cases evaded. New York State, too, the premier and richest and one of the largest States of the Union, is a particularly bad offender in this respect. As Prof. Sedgwick stated, Niagara Falls is, at the present time, one of the worst plague spots in the United States owing to the negligence of State and municipal authorities in disposing of its sewage. But there are many other places in the State besides Niagara Falls which can be pointed at with the finger of scorn on this account. Even New York City itself is by no means free from the reproach of disposing of its sewage in an ineffective and inadequate manner. However, these are truths that he who runs may read, and the purpose of this article and like articles is to persuade the people of the State that it would be better for all concerned if radical changes were introduced in existing methods of getting rid of sewage.

It is obvious, or should be, to any intelligent person that to discharge sewage into streams, in addition to being a gross offence against æsthetics, is more frequently than not a distinct and flagrant menace to the public health. In the instance of Niagara Falls it is assuredly both. The Falls are more than a national property, they belong to the world, and to permit the beauty and grandeur of the scene to be marred by the sight of ugly iron pipes discharging foul matter into a most picturesque part of the river is an act of vandalism. It is a menace to the public health in that the thousands of visitors who come from all portions of the globe are exposed to the danger of infection. This has been proved by results. As said before, Niagara Falls, although the most conspicuous, it but a single example of the indifference of the people of New York State to the pollution of its streams. A considerable amount of this *laissez aller* policy is due to ignorance. The ordinary individual does not realize the extent of the danger.

Prof. Sedgwick has drawn attention to what he deems to be, to a large extent, a popular delusion. He is of the opinion that the once universally held dictum that "running water purifies itself" must be accepted with many modifications. To rely upon this statement is to lean upon a broken reed. It has been disproved times without number. True, if given sufficient time running water will purify itself, but before it has done so it may spread infection near and far. Indeed, a strict adherence to this view is dangerous, and more than one large epidemic of typhoid fever or cholera has been disseminated by faith in this sanitary fallacy. A remarkable instance, or what seems to have been a remarkable instance, of the fallacy of trusting to this theory has been exhibited in the case of Montreal. Here is a city of not more than 500,000 people, who take the greater part of their water supply at a distance of six or seven miles from the city from one of the largest and apparently one of the cleanest rivers of the world and yet typhoid fever, on a large scale, is at more or less frequent intervals breaking out in the city. The St. Lawrence is a fairly rapid river, but it seems unable to purify the upstream sewage of no great mass before it reaches the intake. It would be a mere waste of time to multiply examples of this kind, they abound everywhere. If it be desired to obtain a pure water supply from a running stream, either sewage must not be discharged into it, or such sewage must be effectually rid of its noxious and offensive qualities ere this is done. After all, this is the crux of the problem of how to procure a pure water supply from a stream.

AN IMMUNIZING SERUM FOR ANTERIOR POLIOMYELITIS.

DURING the past two years, owing to several extensive epidemics of anterior poliomyelitis, both in America and Europe, opportunities have been offered for a considerable amount of systematic investigation into the etiology and nature of this disease. That these opportunities have not been wasted is evidenced by the large number of articles which have appeared in the medical periodicals during the past few months, reporting, link by link, the chain of discoveries made by Flexner and Lewis in this country and by Landsteiner, Römer, and others in Europe. The infectious nature of the disease was shown by inoculations into monkeys and the possibilities of study were enormously increased by the ability to transmit the disease from monkey to monkey. Much has been learned as to the nature of the virus, its permeability to bacteria proof filters, and its viability under various conditions. Among the more recent disclosures as to the disease is the fact that one attack renders an animal immune to a second infection, that a monkey which has sur-

vived a mild attack of poliomyelitis may receive further inoculations with an active virus without showing renewed signs of the disease.

Another step of importance has been taken recently by Römer and his coworker, Joseph, and reported in the *Münchener medizinische Wochenschrift* for March 15, 1910. Having obtained three monkeys which had been inoculated with an active virus, and had had typical attacks of the disease, but had survived, their immunity was proved by repeated injections. Blood was then drawn from these three monkeys, and also from a control animal, which had previously received no inoculation. The sera from these four blood specimens were then mixed with active virus of poliomyelitis, and the resulting mixtures, after standing one hour at 37° C. and twenty-three hours at 15° C., were inoculated into fresh monkeys. The animal receiving the mixture of virus and normal serum promptly developed the disease, became paralyzed, and died, while those which were given the mixture of virus and serum from the immunized animals remained perfectly well. These experiments, in so far as one is warranted in drawing conclusions from such a small series of tests, show the possibility of obtaining an active antitoxic serum from the blood of immunized monkeys which has the power of protecting the normal animal against the virus of anterior poliomyelitis.

At the rate at which the advance in our knowledge of the cause and prevention of this dread disease in childhood, as occurring in the monkey, has been made within a few months, it would cause but little surprise to learn at any time that the bridge between experimental research and practical therapeutics had been crossed, and that an actual cure, or at least a preventative against the disease, had been obtained. The work on poliomyelitis in man and the monkey gives promise of standing forth like that on cerebrospinal meningitis as a brilliant justification in the eyes of the world of the inestimable value of animal experimentation and laboratory research in the prevention and alienation of suffering and disease.

Polar Hygiene.

Among the most harrowing chapters in the writings of explorers, a few decades ago, were those describing the sufferings which they and their companions underwent, as a result of disease. This was especially so in the works of the men who for so many years have risked their lives in the search for the North Pole, who have been separated from civilization for months or years at a time, and have been obliged to live during the long Arctic nights huddled together in quarters which at times reached the acme of insanitation, in the cabins of ice-bound ships or closed huts built upon the desert of ice. It is not surprising that these explorers, wasted by scurvy, by bad nourishment, and by fevers, were year after year forced to turn back from their quest, and to return to civilization, but mere shadows of their former selves. Each year, however, as a knowledge of hygiene in general and of hygiene under these especial conditions has increased, the explorers returning from the frozen parts of the earth have reported that they have come nearer and nearer to their goals, until last year it was stated that they had at last reached the North Pole and had come within almost one hundred miles of the South Pole. To one looking upon the health conditions of such expeditions a few years ago, and comparing them with the article by A. Forbes Mackay, surgeon to Lieutenant Shackleton's Antarctic expedition, which has appeared in the *Edinburgh Medical Journal* for March, 1910, one explanation of the recent successes of Peary and of Shackleton is strongly suggested. In reporting upon the health of the party of fifteen during their sojourn of fourteen months within the Antarctic circle, the surgeon of the expedition is obliged to confine himself to the consideration of frost bites, snow blindness, and chapped lips. His remarks upon these subjects are interesting, but far more instructive is the fact that returning from such an expedition he has no other cases of illness to report. To quote Mackay's own words: "We had not a trace of scurvy, no coughs or colds, no anemia, zymotic diseases, no rheumatism. Some members of the party suffered slightly from dyspepsia during the winter, but this might be ascribed to large appetites and little exercise. We felt none of that depression of spirits of which gruesome pictures are painted by some polar explorers. This was due mainly to the hearty feeling of good-fellowship kept up by the old hands, and soon copied by the new. Besides this, our hut was so small that there was nowhere for a man to go and sulk, and outside it was too cold." Without in any way detracting from the credit due to the leaders of the recent exploring parties, it seems highly probable that the steady advance in polar exploration is largely due to the modern appreciation of hygienic laws, and their careful application to the existing conditions by the surgeons who accompany such expeditions.

Skunks as Transmitters of Rabies.

Dr. John C. Janeway, assistant surgeon U. S. A., published, in the Medical Record, March, 1875, a paper in which he reported ten fatal cases of rabies from skunk-bite, on the then Kansas frontier. Since that time several cases of rabies from skunk bites have been recorded in Arizona. C. E. Yount of Prescott, Ariz., read before the eighteenth annual session of the Arizona Medical Association, May 20, 1909, a paper on the subject, which was published in the *Southern California Practitioner*, March, 1910. In this paper it is shown that from May, 1907, to May, 1909, eighteen individuals were bitten by skunks, of which number five developed rabies and died. All the cases but one were treated. One was treated by permanganate injection, three had no Pasteur treatment, while twelve were treated by the Pasteur method. Of those who died, one was not treated, three had no Pasteur treatment, while one had Pasteur treatment. The skunks attacked the persons bitten, generally when sleeping in tents or in the open, and the writer is inclined to regard this fact, taking into consideration the usually timid habits of the animals, as *a priori* evidence of rabies and as an indication for Pasteur treatment. Yount reviews the methods of treatment and points out that in all circumstances, whenever an individual is bitten by a dog or other animal, cauterization should be resorted to at once, and if the wound is upon an exposed portion of the body, the patient should be subjected to the Pasteur treatment whenever possible and as quickly as pos-

sible. The object of treatment by this method is to establish an immunity, and this is why the employment of the serum of an animal highly immunized is advised in badly bitten and late cases so as to establish a passive immunity pending the acquirement of a more lasting immunity resulting from the inoculation of rabies virus. Antirabic serum, in fact, is likely to be of limited benefit, allowing that in rabies the virus is a germ and not a toxin, and in consequence assuming that the serum of an immune animal is antimicrobic rather than antitoxic, as said before its use is to establish a passive immunity, until by the regular Pasteur treatment an active immunity can be obtained. In any event, prompt treatment should be the watchword. In the United States there is a considerable amount of rabies always present, and in most districts the disease can be abolished in time by muzzling and shutting up dogs. But when, as in Arizona, the disease is conveyed by skunks, the only effectual means of eradicating it is by doing away with the cause, that is by destroying the skunks. If this is not practicable, then a Pasteur institute should be forthwith established in Arizona, as although there is yet much to learn concerning rabies the evidence is sufficient to establish the fact that the Pasteur treatment is to a great extent effective.

Action of the Products of the Tubercle Bacillus on Lymphatic Organs.

In the laboratories of the State Department of Health of Pennsylvaniia, experiments have been undertaken recently to observe the effect of repeated injections of the products of the tubercle bacillus on lymphatic organs. The reason for these experiments was that the condition of the spleen in guinea-pigs after treatment with tuberculin or some product of the tubercle bacillus suggested that this organ might be the seat of some pathological change caused by these injections. The first animal experimented upon was a healthy cow, into which was injected six times, two weeks apart, 400 milligrams of old tuberculin under the skin. She did not react at all, and when killed, two weeks after the last dose, at the autopsy appeared to the naked eye to be a healthy animal, no areas of necrosis or focal development suggesting tubercles being found in the lymph nodes; the glands in some instances were somewhat hyperemic, but the spleen showed no distinct changes nor did the liver. In fact, the results of this experiment demonstrated that the treatment produced no distinct focal necroses. There was, however, a tendency to hyperplasia of the endothelium, which went on to vacuolization and necrosis. This was more diffuse than usually seen in guinea-pigs' spleens, and affected frequently the sinus and endothelium. In both the cow and guinea-pigs the endothelium suffered, but Dr. Dixon and his coworkers attribute this degeneration to great proliferation incident to the toxemia. In a broad way it may be said that the effect of tuberculin on normal guinea-pigs, either in one or two large doses or in many small ones, is seen especially in the lymphatic follicles. In guinea-pigs primarily injected with tubercle bacilli and treated with tuberculin, the process is very rapid. The tubercle bacillus toxin injected into healthy animals in minute or large doses has little effect upon lymphatic organs. The essential effect of all the products injected was a stimulation of endothelial cells, the stimulation varying with the products employed.

News of the Week.

Health Conditions in the Canal Zone.—The February, 1910, report of Col. Gorgas of the Isthmian Canal Commission shows an annual average per thousand of deaths from all causes among employees of 8.75, as against 9.42 for the corresponding month of last year and 12.80 for February of 1908. The death rate per thousand for the entire population of the Canal Zone and the cities of Panama and Colon was 17.50, as against 18.59 for the corresponding month of last year and 21.40 for the month of February, 1908. No cases of yellow fever, plague, or smallpox originated on or were brought to the isthmus during the month.

A National Milk Investigation Proposed.—A resolution was offered in the House of Representatives by Representative Parsons of New York, recently, calling attention to the spread of tuberculosis and typhoid fever by means of milk, and asking that an immediate investigation of the subject be undertaken by the House Committee on Agriculture.

Cold Storage Investigation.—A resolution has been offered by Senator Heyburn in the United States Senate to the effect that the Committee on Manufactures be authorized to have hearings to ascertain the quantity of meat, eggs, and other food held in cold storage, and to discover the effect of cold storage upon these foods.

Immigration Laws Waived.—The immigration laws forbidding the entrance into the United States of an alien suffering from tuberculosis were set aside recently in the case of an Englishman who was coming to this country with his wife and family in search of health in Colorado. The entire family was taken to Ellis Island where they were detained for several days until the order for their release arrived from Washington. The patient was allowed to proceed after giving bond that he would remain in Colorado and would not become a permanent resident.

A Gold Medal for Dr. Robert Fletcher.—The Royal College of Surgeons of England has awarded a gold medal to Dr. Robert Fletcher, principal assistant librarian in the library of the Surgeon-General's office in Washington, in recognition of his services in connection with the publication of the catalogue of the Surgeon-General's library and the editing of *The Index Medicus*.

Dental Clinics in England.—An anonymous philanthropist has offered the sum of $100,000 to found dental clinics in England where the poor may receive treatment at a small cost.

A Board of Inebriety for New York City.—The New York State Assembly has passed a bill, prepared by Assemblyman Lee, empowering the Board of Estimate of New York City to authorize the appointment of a board of seven men to be known as the Board of Inebriety. Two members of the board are to be physicians and the Commissioner of Public Charities and the Commisioner of Correction shall be members *ex officio*. The board is given authority to purchase a site for a hospital and industrial colony for the care and treatment of inebriates within or without the city of New York. If outside, provision is made for a reception hospital within the city limits. General provisions are also made in the bill for keeping track of persons arrested for intoxication.

A Dinner to General Wood.—A dinner was

given to Gen. Leonard Wood, in Havana, on April 13, by Dr. Guiteras and other sanitarians who worked under him when he was Governor-General of Cuba. In a speech Dr. Guiteras congratulated Gen. Wood upon being "the pioneer warrior to establish health in the tropics."

Dr. George H. Knight of Salisbury, Conn., has been appointed by Governor Weeks to fill the vacancy on the State Tuberculosis Commission caused by the death of Dr. J. P. C. Foster of New Haven.

Philadelphia Hospital.—Dr. Hubley R. Owen has been appointed visiting surgeon in the place of Dr. J. Chalmers Da Costa resigned.

The Northern Medical Association of Philadelphia held its tenth annual banquet on the evening of April 11. The event was made the special occasion for the celebration of the fiftieth anniversary of the entrance on the practice of medicine of Dr. J. Solis-Cohen, honorary professor of laryngology in Jefferson Medical College and at one time President of the Association.

Dinner to Dr. William H. Welch.—A dinner was given in Baltimore, on April 2, in honor of Dr. William H. Welch. It was attended by 500 friends and former pupils, and was the occasion for the subscription for a medallion, designed by Mr. Victor D. Brenner.

An Organization of Children's Clinics Proposed.—A proposition was offered by Dr. Goldwater of Mount Sinai Hospital before the Section on Public Health of the New York Academy of Medicine, recently, that an organization of all the children's clinics in New York City be founded, the new organization to be closely associated with the New York Milk Commission and the various societies which are working for the betterment of the children of the city.

A Strike in a Medical School.—Thirty students of the Medical Department of Washington University went on strike recently as the result of the suspension of a student for smoking in the library. When the strikers attempted to return to their studies they were informed by the dean that by their action they had severed their connection with the school and could be reinstated only by application to the faculty.

Attempted Burglary in a Hospital.—Robbers recently broke into the office of the German Hospital in San Francisco and attempted to crack the safe. They were frightened away before they had secured anything of value.

A Mother at the Age of Ten Years.—In the Cook County Hospital a few days ago a girl baby was born to a mother herself said to be only ten years of age. The case is being investigated by the Juvenile Court.

Physicians Suspended from Bellevue.—As a result of the newspaper stories published recently complaining of the poor food served to the house staff in Bellevue Hospital, two of the house staff who were concerned in having the reports published have been suspended by the superintendent pending the action of the Board of Trustees. It is a rule that internes shall not talk with interviewers or others on matters pertaining to the management of the hospital.

A New Tuberculosis Camp in Topeka, Kan.—The Topeka Provident Association has secured fifteen acres of wooded land in North Topeka for the establishment of a temporary tuberculosis camp. The land was rented for one year, with the privilege of using it for five years if needed.

Alive at 110 Years.—A colored woman, an inmate of the Home for Aged and Infirm Colored Persons in Philadelphia, has just celebrated what is claimed to be her one hundred and tenth birthday. The record of her birth is in a family Bible.

The Simon Baruch Bath.—The new public municipal bath opened recently in Chicago has been named after Dr. Simon Baruch of New York in recognition of his active work in advocating public baths throughout the country.

A New Hospital for the Catholic Protectory.—Plans have been filed for a new two-story hospital building for the use of the inmates of the New York Catholic Protectory.

The Junior Sea Breeze Hospital, which has been in existence for four years on the grounds adjoining the Rockefeller Institute for Medical Research, and has been supported entirely by Mr. Rockefeller, will open for its fifth season in the middle of May for the care of sick infants. The hospital has accommodations for sixty infants. The attending physicians are Dr. Philip Van Ingen and Dr. Royal S. Haynes.

A Vivarium at Princeton.—A new addition to Princeton University which will soon be completed is a "vivarium." This building will belong to the biological department, and in it will be kept live mammals, birds, insects, fish, and the lower forms of animal life for the purposes of study and investigation. A greenhouse and botanical garden are also included in the plan.

The Drake Medical School, which recently absorbed the Keokuk Medical College, is to go out of existence at the end of the present term, according to a recent vote of the faculty, as it has been decided that it is impossible with their present finances to keep up to the standard required of a medical college. Efforts are being made by students and alumni to raise sufficient money to avert this necessity.

The Undergraduate Medical Research Club of Tulane University of Louisiana is a new organization whose name describes its purpose. Mr. Waldemar Metz has been elected president.

A Failure of the Emmanuel Movement.—The experiments which have been carried out at St. Luke's Hospital in San Francisco with the Emmanuel movement have been discontinued. The reason which has been given for the failure of the experiments is that the depressing effects of a general hospital makes it impractical to carry out the Emmanuel method of treatment in a ward connected with such an institution.

State Hospital Notes.—Dr. William L. Russell, formerly first assistant physician at the Willard State Hospital and for nearly seven years medical inspector of the New York State Commission in Lunacy, has been appointed superintendent of the Long Island State Hospital at Brooklyn to succeed the late Dr. Oliver M. Dowing. A promotion examination open to first assistant physicians will be held on April 27 to secure an eligible list from which another medical superintendent and a new medical inspector shall be chosen.

Rabies at White Plains.—Three dogs belonging to the pack of the Westchester Hunt Club developed rabies recently and bit several other dogs in the kennels. The entire pack, valued at $2,000, was killed at once.

Mount Sinai Hospital.—A gift of $130,000 has been made to Mount Sinai Hospital by Mr. Adolph Lewisohn toward the erection of a pathological laboratory to be known as the Mount Sinai Pathological Laboratory. Adolph Lewisohn Foundation. Mr. Lewisohn has previously given $70,000 to the pathological laboratory of the hospital.

The Henry Hobart Mason Memorial Hospital is to be built in Great Barrington, Mass., as the result of a bequest of $500,000 from the late Mrs. Mary A. Mason of Great Barrington.

Charitable Bequests.—By the will of the late William Hyams of New York the following institutions were among those receiving bequests: Mt. Sinai Hospital, $1,000, and Beth Israel Hospital, $5,000. At the death of Mrs. Hyam the Mt. Sinai Hospital will receive $5,000, the Montefiore Home, $5,000, and the Lebanon Hospital, $1,000. By the will of the late Maria Snyder of Philadelphia the sum of $3,000 is bequeathed to the Methodist Hospital.

The Canadian Medical Association will hold its forty-third annual meeting in Toronto, June 1 to 4, 1910. The president of the association is Dr. Adam H. Wright, and the general secretary is Dr. George Elliott, 203 Beverley street, Toronto. The address on medicine will be delivered by Dr. Herringham of London, England, and the address on surgery by Dr. Murphy of Chicago.

The American Medical Editors' Association will hold its annual meeting at the Planter's Hotel, St. Louis, on June 4 and 6, 1910. The president of the association is Dr. W. A. Young of the *Canadian Journal of Medicine and Surgery*, and the secretary-treasurer is Dr. Joseph MacDonald, Jr., of the *American Journal of Surgery* of New York City.

The National Association for the Study of Epilepsy and the Care and Treatment of Epileptics.—The next meeting of this association will be held at Baltimore, Md., on May 7, 1910. The meeting is held there by invitation of the Maryland Psychiatric Society. Further information may be obtained from the secretary, Dr. J. F. Munson, Sonyea, N. Y.

The New York Society of Radiology and Physical Therapeutics will hold its next meeting at the Academy of Medicine, April 29, 1910, at 8.30 P.M. The subject will be "A Symposium on the Treatment of Tuberculous Adenitis."

Pennsylvania Society for the Prevention of Tuberculosis.—At the annual meeting, held April 13, Dr. James Tyson was selected president for the ensuing year in succession to Dr. Chas. J. Hatfield.

The Interior Medical Society of Mexico, at a meeting held at Mexico City, March 30, 1910, elected the following officers for the coming year: *President,* Dr. Antonio Loaeza; *Vice-President,* Dr. Octavio Gonzalez Fabela; *Secretary,* Dr. Jose Escalona; *Treasurer,* Dr. Everardo Landa; *Second Secretary,* Dr. Demetrio Lopez.

The Hartford County (Conn.) Medical Association held its 118th annual meeting April 5, 1910. The following officers were elected: *President,* Dr. Hermann Strosser of New Britain; *Vice-President,* Dr. Harmon G. Howe of Hartford; *Secretary and Treasurer,* Dr. Frederick B. Willard of Hartford; *Councilor,* Dr. O. C. Smith of Hartford.

The Hillsborough County (N. H.) Medical Society, at a meeting held in Manchester, April 6, elected officers for the coming year as follows: *President,* Dr. John H. Gleason; *Vice-President,* Dr. H. L. Smith of Nashua; *Secretary and Treasurer,* Dr. Ella B. Atherton of Nashua.

The New London County (Conn.) Medical Society held its 119th annual meeting at New London, April 8, 1910. The election of officers for the year 1911 was as follows: *President,* Dr. Patrick J. Cassidy of Norwich; *Vice-President,* Dr. E. C. Chipman of New London; *Secretary and Treasurer,* Dr. E. Oliver Winship of New London; *Censors,* Dr. Rush W. Kimball of Norwich and Dr. F. M. Braman of New London.

The Connecticut Society of Alienists held a meeting at Bridgeport, March 29, 1910, under the presidency of Dr. D. W. McFarland of Greens Farms.

The Butler County (Neb.) Medical Society held its annual meeting April 6, 1910, at David City. The following officers were elected: *President,* Dr. F. J. Swoboda; *Vice-President,* Dr. E. D. Sanghardt; *Secretary and Treasurer,* Dr. H. E. Marselus.

The Golden Belt Medical Society held its annual meeting at Salina, Kan., April 8, 1910. The following officers were elected: *President,* Dr. O. D. Walker of Salina; *Vice-Presidents,* Dr. W. D. Whitmer of Abilene and Dr. J. D. Colt of Manhattan; *Secretary,* Dr. L. O. Nordstrom of Salina; *Treasurer,* Dr. W. S. Harvey of Salina.

The Late Dr. A. H. Smith.—At a special meeting of the Board of Directors of the New York Post-Graduate Medical School and Hospital, held on April 11, 1910, the following resolutions were adopted and spread upon the minutes: *Whereas,* Andrew Heermance Smith, M.D., LL.D., Vice-President of the New York Post-Graduate Medical School and Hospital since March, 1895, was removed by death from our midst on April the eighth inst., we, his colleagues and fellow laborers desire to record our tribute of affection and high esteem for him as a man, a friend, a teacher of medicine, and an executive officer, and, *Whereas,* his character was a noble one; his principles of the highest order; his loyalty to duty and to his friends sincere; his attainments those of a scholar, and he was laden with the honors of his chosen profession, the welfare of this institution was ever uppermost in his heart, and he ever lent his best efforts to promote its interests, be it therefore *Resolved;* That we mourn him as a great man among men, and while expressing to his widow and family our deep sympathy in their bereavement, we court the privilege of addressing to them a copy of this resolution.

Obituary Notes.—Mrs. HUNTER ROBB died in Cleveland, O., on April 15. As Miss Isabel Hampton she was the first superintendent of nurses and thus the founder of the training school of the Johns Hopkins Hospital, and since her marriage she has been chairman of the training school committee of the Lakeside Hospital in Cleveland. Mrs. Robb was also one of the founders of the Society of Superintendents of Training Schools for Nurses, and the Nurses' Associated Alumnæ of the United States, and was influential in the formation of the course in hospital economics in the Teachers' College of Columbia University.

Dr. JONATHAN E. TEFFT of Springfield, Mo., died at his home, March 25, 1910, aged 74 years. He was a graduate of the Medical College of Ohio in 1865, and was in charge of the Federal Hospital at Cassville, Mo., during the Civil War. He was a member of the Greene County Medical Society,

the Mississippi Valley Medical Association, and the American Medical Association, a former president of the Missouri State Medical Association. Dr. Tefft was senior surgeon to St. John's Hospital from the date of its foundation.

Dr. JEROME KEELEY of Georgetown, Pa., died on April 4 of pneumonia at the age of 84 years. He was a graduate of the Medical Department of the University of Pennsylvania and he was engaged in the practice of his profession for a number of years in Lionville and Atglen, Pa.

Dr. JOHN L. WARREN of West Chester, Pa., died of pneumonia on April 8 at the age of 72 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1856. He was a direct descendant of General Warren of Bunker Hill fame.

Dr. FRANCIS W. WATSON of St. Louis, Mo., died at his home, March 28, 1910, aged 67 years. He was a graduate of the Rush Medical College in 1866, and practised in Eureka, Kan., until retiring two years ago.

Dr. THOMAS NEAL MCLEAN of Elizabeth, N. J., died at the Johns Hopkins Hospital in Baltimore on April 8, 1910, aged 67 years. He was a graduate of Yale University in 1866 and the Yale Medical School in 1871. He was a member of the Union County Medical Society and of the Medical Society of New Jersey.

Dr. SAMUEL PIERPONT LADD of Moosup, Conn., died suddenly April 6, 1910, aged 62 years. He was a graduate of New York University in 1879.

Dr. JAMES O. PINGRY of Millbrook, N. Y., died at his home, April 10, 1910, aged 66 years. He was a graduate of the College of Physicians and Surgeons of New York in 1868, and was a member of the Alumni Society of Bellevue Hospital, the Dutchess County Medical Society, and the Medical Society of the State of New York.

Dr. HENRY SHAW of Boston, Mass., died March 28, 1910, aged 80. He was a graduate of the Harvard Medical School and began practice in Upton in the late fifties. In 1861 he was elected to the Legislature and in 1862 entered the navy. After the war Dr. Shaw practised in Bedford, but retired thirty years ago to devote his time to charitable work. He was for many years Clerk of State Aid at the State House.

Dr. GARDNER PERRY POND of San Mateo, Cal., died March 19, 1910. He was a graduate of the medical department of the University of California in 1893, and practised for several years in San Francisco. He was a member of the San Mateo County Medical Society, the Medical Society of the State of California, and the American Medical Association.

Dr. WILLIAM JACOB POINTS of Harrisburg, Mich., died at his home, March 24, 1910, aged 78 years. He was a graduate of the Washington Medical College in Baltimore in 1852. He however gave up the practice of medicine in 1865 and studied law, since which he has held many government positions.

DR. WILLIAM W. COLEMAN of Mount Washington, Ky., died at his home, March 30, 1910, aged 56 years. He was a graduate of the Medical Department of the University of Louisville, in 1883, and was a member of the Bullitt County Medical Society and the Kentucky State Medical Association.

Dr. WILLIAM RUSSELL of Minneapolis, Minn., died recently, aged 68 years. He was a graduate of the University of Michigan, 1877.

Correspondence.

DR. MELTZER'S LETTER ON MY PARTICIPATION IN THE SYMPOSIUM ON THORACIC SURGERY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Dr. Meltzer's letter, published in the MEDICAL RECORD of the 2d inst., has been read. Its tone comes as a surprise to me and is greatly regretted. My regard and esteem for Dr. Meltzer as a colleague and scientist are too great to permit me to enter into a discussion with him on the basis of this letter. The proper answer to it would be none, were it not that certain of his allegations, if left uncontradicted, might be accepted as facts by those not familiar with the circumstances. In justice to myself, therefore, it becomes necessary for me to make a reply.

It would take another paper to set aright all of Dr. Meltzer's many misinterpretations and misconstructions of words, phrases, and arguments contained in my article, "Avoidance of Apparatus Complicating the Operation a Paramount Requirement in Thoracic Surgery" (MEDICAL RECORD, March 19, 1910), in which is discussed the continuous intratracheal insufflation method advocated by Dr. Meltzer. I thought I had to discuss it at some length, as well as a participant in the symposium which was the outgrowth of Dr. Meltzer's announced paper, the title of which became the topic of the evening, as also as a general surgeon, deeply interested in everything pertaining to thoracic surgery. Moreover, Dr. Meltzer, many months before reading his paper, had invited surgeons with whom he came in contact "to judge for themselves whether and when his method might be applied to human surgery." In order to arrive at any conclusion regarding the value of a method, a critical examination into all of its features is necessary and should be welcomed by its author rather than give rise to unkind feelings toward the critic. I am satisfied that I have advanced my criticisms with the greatest moderation and with due regard for Dr. Meltzer's feelings.

What appears to have irritated Dr. Meltzer more than anything else is my use of the designation "blowpipe method" for the rather long name of "Meltzer-Auer continuous intratracheal insufflation method." Obviously, the latter was too cumbersome an expression for frequent repetition. I therefore tried to find a suitable abbreviation. "Insufflation method" was considered inappropriate because that would have included the old style intermittent insufflation; "intratracheal insufflation method" would have included Kuhn's, with which I wished to contrast Dr. Meltzer's. It became necessary, therefore, to find some other expression, and the short substitute used by me seemed to me most to the purpose. I have to confess that I did not look up the meaning of the word in the Century Dictionary, as Dr. Meltzer did, but the use of a word in one discipline does not prohibit its use in a different sense in another branch of science, if properly explained. Moreover, it will be noticed that the abbrevation "blowpipe method" is employed only in the text of my paper, while in headings and in the conclusions the full name is always used, which alone might have been sufficient to convince Dr. Meltzer that no discourtesy was intended.

Dr. Meltzer next accuses me of inaccurate quoting, and finds it in a footnote where I quote from memory. The alleged inaccuracy is contained in my saying dust had been deposited on the wall of the trachea, when Dr. Meltzer has it that the dust was blown out of it. But I there argued on the *direction* in which the dust traveled, as indicative of the direction of the air current. In this respect Dr. Meltzer's statement and mine are identical. For the point under discussion it is quite immaterial and irrelevant where the dust settled, and *not*, as Dr. Meltzer says, "quite essential," so that his accusation falls to the ground. Another alleged inaccuracy refers to my remark: Dr. Meltzer had said in a discussion at the International Congress at Berlin, in 1890, that "with the glottis open, as in intubation, aspiration of foreign matter into the lung was impossible," in reply to which Dr. Meltzer says in his letter: "What I said was that pneumonia, etc., cannot develop while the glottis is open, and not that no aspiration can take place." In the discussion from which I quoted in my paper and which deals with aspiration pneumonia, Dr. Meltzer places in opposition the inhalation of foreign bodies

by aspiration when the glottis is open—which he denies—and by a back-current (Ruecklaeufiger Strom) when the glottis is closed—which he affirms. I fail to see any difference between what I quoted him as having said and what, according to the official report, he actually did say, so that in this instance again his accusation is without foundation.

In his letter Dr. Meltzer states I had raised the objection that "intubation was a difficult procedure." At no place in my paper nor at any other place have I made that general statement. What I did say is that intubation requires experience, and further, under the heading of "Difficulties of Intubation and Contraindications" (p. 485, line 14), that cases are met with in which intubation is a physical impossibility, and others in which it is contraindicated.

Furthermore, Dr. Meltzer would have the readers of his letter believe that it had been my intention to "choke off the life" of the method he has worked out, "while it is still in its infancy." Just the contrary is the fact. Not only is it stated in my paper that I was contemplating the use of Dr. Meltzer's method myself in certain cases, when sufficiently perfected apparatus should be available for practical use on the human being, but in addition to that I have tried, from the standpoint of the general surgeon, to point out the direction which such improvements should take, in order to make the apparatus thus available and in order to give to the surgeon employing it something approaching the confidence he feels in his apparatus, when using one of the larger differential-pressure chambers in this difficult and responsible work. I did not concern myself with the possible broader aspects of continuous intratracheal insufflation, but only with its application to thoracic surgery on the human being.

Dr. Meltzer's treatment of my physiological discourse has in no way shaken my conviction that continuous intratracheal insufflation is a positive differential-pressure method. Surgeons, making use of it, can therefore work with positive pressure only. On the other hand, it has been one of my aims in connection with the work that I have been permitted to do at the Rockefeller Institute to develop apparatus based on the recognition of the fact that the question of whether negative and positive pressure have the same effect upon patients in the various thoracic diseases is still an open one, apparatus which renders possible the application of both kinds of pressure during one and the same operation without interruption. This work was undertaken *after* a careful study of all the then existing apparatuses as well as the literature on the subject, and when it came to publishing my results due credit was given to all who had worked previously in the field.

In conclusion I wish to say again that I have replied to Dr. Meltzer only to set myself right in the eyes of the readers of his letter. I must decline to take up the discussion of a scientific subject by open letter. For my part this correspondence is herewith closed.

WILLY MEYER, M.D.

April 14, 1910.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SURGERY IN ABDOMINAL DISORDERS—FORMS OF ARTHRITIS—SPINAL ANESTHESIA—SIR A. KEOGH—CASE OF HYDROPHOBIA—OBITUARY.

LONDON, April 1, 1910.

WE are still talking about abdominal surgery in what have long been considered medical cases. Gastric, duodenal, enteric, and even appendicular dyspepsia are phrases you may hear when doctors casually meet and even in set discussions at societies. The physicians still claim that functional indigestion is something which the operating surgeon has not yet completely explained, and general practitioners mostly agree with them and profess familiarity with hyperchlorhydria, achylia, biliary disturbance, reflex irritation, and numerous other causes of deranged digestion. Everyone admits that organic disease of any part of the alimentary canal, of any degree of severity, is met with under various conditions and is sometimes rather difficult to differentiate. Have not the surgeons often been called to operate too late in perforated ulcer, and are they not right to demand early diagnosis and early operation? Exploratory opening of the abdomen has come to be regarded as practically a safe proceeding. At the same time caution is to be inculcated in presence of the fact that operations have been performed on insufficient indications and no lesion discovered. Even if we take the most easy view of this error, it must seem less excusable to the patients. Statistics of success are too often carelessly quoted and are in some senses meaningless. Thus it was argued the other day that one surgeon had had such a percentage of appendix dyspepsia, to which the answer was that he was the chief operator of a large hospital and that the physicians to it were all on the lookout since the question had been raised and turned over such cases to him. His experience, then, could be no indication of the frequency of such cases, and a senior general practitioner said it was idle to talk of percentage when he had had thousands of patients with dyspepsia and only one with a symptom suggesting an appendicular origin, and that one had not proved to be such.

Opinion seems to be settling down in favor of operation when there are definite indications of a lesion of the stomach or duodenum, which are sufficiently distressing to induce the patient to consent. That without such definite signs operation is not to be undertaken. In all cases where the abdomen is opened and the expected lesion is not revealed it is only reasonable after the recent statements of experienced surgeons to examine the appendix, latent disease of which appears to be more common than has been supposed and capable of simulating lesions in other parts of the abdomen.

If the surgeons have ascribed so many dangers and inconveniences to be due to the retention of the appendix, and therefore urged its frequent removal, they have on the other hand shown that its possession may be utilized by the physician and their readiness to operate in this direction. In colitis, for example, an appendicostomy enables the bowel to be more thoroughly flushed than it can be by irrigation per rectum. In a discussion on this disease on the 14th ult. at the Medical Society of London this treatment was considered. It is certainly less formidable than colostomy, which, however, seems sometimes the only chance of prolonging life. It is very rare that a cure is effected by this last with a closure of the opening. For flushing all usual liquids may be used. One Fellow had used sour milk in this and every other way, but had never seen any result. For drugs he relied on calomel and opium and remarked that calomel was well borne for long periods. Others recommended castor oil, liquid diet, injection of air, on the supposition that the cause was an anaerobic organism, etc. Obviously cases of less severity, though very tedious, might not be inflammatory and should not be called colitis; they would never call for appendicostomy flushing.

The Section of Balneology and Climatology (Royal Society of Medicine) has begun a discussion on arthritis, but so extensive a subject could not be concluded in one evening and an adjournment has taken place until the 20th. Meantime you may be interested in some of the points put forward. The discussion was opened by one of our spa physicians, Dr. Llewelyn Jones of Bath, who under the title of "Arthritis Deformans" spoke of three groups of cases, viz., (a) rheumatoid arthritis, (b) osteoarthritis, and (c) infective arthritis. As to (a) he regarded its frequent association with an infective or toxic element as a strong point in favor of the view that it was of a similar origin to (c). The early changes affected the synovial membranes and periarticular tissues. Later the cartilages were involved and eventually atrophy of these took place, as well as of other tissues leading to ankylosis. Clinically he defined it as a progressive symmetrical polyarthritis, which might be met with in an acute or chronic state, but always showed remissions and exacerbations, and was accompanied by various collateral phenomena, e.g. vasomotor symptoms, pigmentation, localized sweats, muscular atrophy, splenic and glandular enlargements. As to (b), osteoarthritis was more a joint disease and often connected with trauma, and the primary changes were in bone and cartilage, which hypertrophied, but without ankylosing. Bony outgrowths, however, were found at the articular ends. The synovia was secondarily affected.

In infective (c) arthritis the constitutional symptoms were severe, splenic and glandular enlargements, leucocytosis and anemia, though at first only a few joints were attacked, mostly the larger, the distribution being erratic instead of symmetrical, in this contrasting with (a) as well as in absence of collateral phenomena. Any toxic disorder (typhoid, etc.) might be followed by

arthritis, so might local discharges (otorrhea, etc.), and should be carefully distinguished from acute rheumatoid arthritis. The previous history was of value, as well as existing conditions, from a diagnostic standpoint.

Dr. Fortesque Fox did not think classification founded on the commencement in cartilage or synovia of much use. The disease was degenerative and due to various causes. An infective element was common in early life, in middle life a gouty state, and in late life trauma was frequent.

Dr. Preston King of Bath held that rheumatoid arthritis was the result of various infections rather than a distinct disease.

Dr. Buckley of Buxton admitted that the types put forward were met with, but they were often mixed. Hypertrophic cases he thought were late atrophic ones and showed an attempt at repair and so far a measure of the resistance of the system.

Dr. Hale White held rheumatoid arthritis to be a distinct disease, though its bacteriology was unknown. If similar symptoms were produced by a recognized organism its name should be given to the rheumatoid disease.

Dr. Gardner of Bournemouth was impressed with the importance of soil and the relation to tubercle. Cases often followed arrested tuberculosis and others were followed by ascending degeneration of the spinal cord.

Dr. Gordon Watson recognized two classes, synovial or rheumatoid and bony or osteo, the former infective and the latter traumatic, of which he had seen many cases in young patients following injury to a joint.

Dr. Solly of Harrogate ascribed all cases, whether called rheumatoid, osteo, atrophic, or hypertrophic, to a mixed infection, and the variations of symptoms to the combination of microbes and the proportions present in the different cases. Arthritis often cleared up after the cure of some trivial septic malady.

Dr. Ackerley of Llandrindod Wells would name all cases simply arthritis, regarding that as one manifestation of the disease, and endeavor to find out its origin in each instance. He admitted all forms of sepsis, slight or not, but asked what was it that determined an arthritis in one patient and not in another? He doubted whether any real distinction existed between acute and chronic cases. A smaller dose of toxin or a weaker personal resistance were probable factors.

Treatment was very slightly referred to by the speakers, but will perhaps be more considered at the adjourned meeting. Dr. Humphries, however, made some remarks on the use of electricity and Dr. Middleton said his experience was greatly in favor of continuous counter-irritation. He related a case complicated by exophthalmic goiter.

The miniature hospital for research at Cambridge has for some time been the scene of very earnest work on arthritis. This institution, with only four or five beds, was established for the investigation of chronic diseases, and is under the direction of Mr. Strangeways, lecturer on special pathology in the university, who with his colleagues has seen an immense variety of arthritic cases apart from in-patients. The last Bulletin of the committee contains a careful study of the arterial blood-pressure in arthritic disease and of facts as to the coexistence of infective foci with rheumatic arthritis. Such coexistence is so common that it seems doubtful whether it can be regarded as a mere coincidence. Whether it should be used to set up a distinct variety, as some maintain, is another question. On this and other points we may look for light from the zealous workers at Cambridge.

Unjustifiable statements as to the absence of all danger from spinal anesthesia have been made in some quarters. Deaths have occurred even when strychnine has been given with the anesthetic, as advised by Jonnesco. One is reported by Mr. Milward of the Birmingham Hospital, who was about to operate for acute intestinal obstruction. He had previously operated under this method, in a precisely similar case, without a single untoward symptom, and he very properly suggests that every fatality should be reported. Major Gambett recorded a death in the *Indian Medical Gazette* of last month, as he was about to operate for elephantiasis scroti. He also had employed the Jonnesco method in several cases with complete satisfaction. He attributes the result to the action of the strychnine inducing spasmodic interruption of the respiration. I have heard of some other fatalities, but have not obtained particulars. You will have heard of those on the continent from your other correspondents.

Surgeon-General Sir Alfred Keogh, K.C.B., H.K.P., who last year completed his term as Director-General of the Army Medical Service, has accepted the position of rector of the Imperial College of Science and Technology. He has also joined the Royal College of Physicians.

A coroner's inquest on Saturday last found that the death had been due to hydrophobia coming on six months after the bite of a rabid dog. The victim and another were bitten at Gibralter, where they were serving in the army. They were sent to Paris and underwent treatment at the Pasteur institution. The comrade of the present victim died of the disease about a month after the treatment and his fate seems at times to have preyed heavily on the mind of the later sufferer.

Dr. W. B. Cheadle died on March 25. He had long held a prominent position. He had served the full time as physician to St. Mary's Hospital and become consulting physician. He was a Cambridge graduate, M.A. and M.D., 1865, in which year he joined the College of Physicians as member, and of which he was elected Fellow in 1870. There he gave the Lumleian lectures in 1900. He had previously delivered the Harveian. Both were published, as were various lectures and other contributions. He was also consulting physician to the Hospital for Sick Children and a leading authority on their diseases. He had served as examiner at the college, as well as at Cambridge University.

Another Children's Hospital physician and well-known authority, Dr. George Carpenter, M.D. Lond. 1890, M.R.C.P. 1889, editor of *Pediatrics*, has died at the age of only fifty-one. His "Congenital Affections of the Heart" reached a fifteenth edition, and he was a constant contributor to the societies and journals.

Dr. J. Allan Coutts of Waterfoot, Manchester, died on March 23, aged sixty-six. He had long suffered from heart disease and a year or two ago retired, leaving his son to carry on his practice.

The death is also reported of Dr. Henry Charles Proctor, who held for some time a leading practice in South Africa. During the Zulu war, 1880, he was in charge of invalids from Natal to England. He had served as district surgeon at Harrismith and at Ladysmith and had charge of the Natal Government Railways. He was M.R.C.S. Eng. and L.R.C.P. Ed. and M.D. Brussels.

OUR CANADIAN LETTER.

(From Our Special Correspondent.)

MEETING OF THE CANADIAN HOSPITAL ASSOCIATION—TOPICS DEALT WITH—HOSPITAL ACCOUNTING—SOCIAL SERVICE—NOISE—DEMONSTRATION GIVEN OF A ROOM IN A PRIVATE RESIDENCE ARRANGED FOR CONDUCTING AN OPERATION—VISIT TO THE GENERAL HOSPITAL—PAPER AND DISCUSSION ON HOSPITAL CONSTRUCTION—OTHER PAPERS RELATING TO HOSPITALS—VISIT TO INSANE ASYLUM.

MONTREAL, April 2, 1910.

On Monday, March 28, the Canadian Hospital Association opened its fourth annual conference in the Royal Victoria Hospital, Montreal. Mr. H. E. Webster, Superintendent of the Royal Victoria Hospital, presided. At all the sessions there was a satisfactory attendance, the larger part of the gatherings being ladies. Dr. Guerin, a well-known Montreal physician, who is now Mayor of the city, was present at the opening meeting, and welcomed the delegates in felicitous terms. After Mr. Webster had delivered a brief presidential address, the first paper was read by Dr. Edith Beatty, Toronto. The paper was entitled "The Relation of the Training School to the Hospital Deficit Problem," and was written by Miss Charlotte Aikens, Detroit. The next paper read was of quite exceptional interest. This was by Dr. R. W. Bruce Smith, Inspector of Hospitals, Ontario, and dealt with "Hospital Accounting." It is a fact only too well known to those responsible for the conduct of a hospital that it is extremely difficult to manage a hospital efficiently upon economical lines. It is also a notorious fact that institutions of the nature should be run with as little expense as is compatible with thoroughly effective service. On the one hand there must be no extravagance, while on the other there must be no undue economy. The happy medium is the objective desired. To attain this result entails the expenditure of a good deal of thought, and premises the possession of considerable power of organization on the part of hospital superintendents. As Dr. Bruce Smith

pointed out, subscribers to hospital funds had a right to know how the money was used, and he declared that there ought to be a uniform system of accounting in hospitals. A hospital must be managed as a public trust. Over three million dollars were expended last year on hospitals in Canada, but as there was no uniform system of accounting the position of one hospital could not be readily compared with that of another. It was in the interest of the hospitals to be fair with the public. Dr. Smith gave a description of the manner in which hospital accounting was done in the General Hospital, Toronto, and this description was amplified and explained in detail by Dr. J. U. E. Browne, Medical Superintendent of the General Hospital, Toronto. The system is what is known as the triplicate system. Every order for provisions or other goods is made out in triplicate, so that the superintendent is able at any time to lay his finger on any apparent extravagance in ordering, and thus is able to inquire into the matter, and, if necessary, to countermand the order or to insist that no such error occur again. In fact, it is an excellent check system, and the nurses and shopkeepers soon learn that they must be careful in ordering and in providing, for if they are not they will certainly get into trouble. The system has been so successful in the Toronto hospital that Dr. Browne stated that since its introduction thousands of dollars had been saved to the institution. By the way, the system was borrowed from the New York Hospital in Sixteenth street.

A demonstration was given of a room in a private residence arranged for conducting an operation. This transformation was excellently depicted, but does not lend itself very well to description.

At the afternoon session Dr. Helen MacMurchy of Toronto gave an address on "Social Service"—that is to say, how to assist those who have been discharged from a hospital, but have no position to which to go. The nurse was not necessarily an expert in character, and that was what was needed for this work. They must have people who were willing and able to put their patients in touch with those who could be of real assistance to them. Work in this direction was commenced in Johns Hopkins Hospital, but has been more fully developed in the Massachusetts General Hospital.

Another most instructive and pertinent paper read was that by Dr. H. A. Boyce, Superintendent of the Kingston General Hospital, on "Noise." There is perhaps no matter in connection with hospitals which requires discussion and ventilation more than this one of noise. In these days, if a hospital be situated in a city, it is indeed a difficult matter to avoid noise. In most cases it is impossible, and the only thing to be done is to endeavor to reduce outside noises to a minimum and to insist absolutely that in the interior of the building all unnecessary noises shall be strictly tabooed. Of course, as Dr. Boyce said, the position of the hospital should be so chosen as to be apart from the noise of the city traffic, but this desirable situation is not always attainable. There are old hospitals in cities which cannot well be removed, and in those circumstances zones of silence should be formed in the surrounding streets. The ringing of car bells should be prohibited, street hawking and other city noises should be as far as is possible interdicted.

As to the absence of noise in the building itself, much can be done to bring about this happy condition of affairs by the coöperation of the medical and nursing staff. Further, why should not the wards of hospitals be constructed in such a manner that noise from outside or from other parts of the building is deadened? Colleges of music resort to this procedure. No sound, for instance, is more terrifying and distracting to patients than to be compelled to listen to the moans of another patient recovering from the effects of an anesthetic. Dr. Boyce complained of bells in a hospital, and suggested in their place a system of electric flags. There can be no doubt that noise militates greatly against the recovery of a patient, and especially against the recovery of a neurotic or neurasthenic patient, of which, unfortunately, at the present time there are so many. Any steps, therefore, tending to reduce noise in hospitals should be welcomed.

The members of the conference paid a visit to Montreal General Hospital, which is in process of reconstruction, and saw much to interest them.

In the evening Mr. J. H. C. Parke, Superintendent of the Montreal General Hospital, explained by means of diagrams the plans for the reconstruction of the institution. The hospital is situated in the heart of the slum district of Montreal—and Montreal has her slums—and the problem before those concerned with its reconstruction is by no means easy. It is intended to build, or to add, on the present site, which is on different levels. The resolution has been come to to build to a considerable height. The center new building will be nine stories high, and the wings each seven stories. The basement will be utilized for cold storage purposes, as, unlike most hospitals, which buy their provisions from week to week, at the General Hospital large quantities are bought at one time, which necessitates a good deal of space for cold storage. A special feature of the construction of the new buildings is that the entire floor will be employed as an outpatients' department. The medical and surgical divisions will be kept apart on either side of a large entrance, and the waiting hall placed in the center. On the first floor will be the semi-private wards, with a gallery at the end. The administration rooms and operating theaters, which will be together, will be situated at a distance from the wards, the elevators being between them. On the floor above will be the private wards, thirty-nine in number, and of varying sizes. The remainder of the building will be taken up with public wards except that on the eighth floor of the center building will be the dining-room. On the top floor is to be the kitchen. The buildings throughout will be fireproof. The whole structure will be 317 feet long and 135 feet high, which is the city limit. The total number of beds will be 450.

Mr. Meyer J. Sturm of Chicago, hospital architect, gave an address in one of the operating theaters on "Practical Idealism in Planning Hospitals."

On Tuesday morning, March 29, Dr. J. U. E. Browne gave a graphic description, aided by illustrations on the screen, of the magnificent hospital which is to be built in Toronto.

Dr. C. K. Holmes of Cincinnati, Ohio, gave an address on "The Hospital Unit." This was both a practical and idealistic address, and was most instructive. In Cincinnati a new hospital is to be erected, and Dr. Holmes has inspected with the eye of an expert and with great enthusiasm all the principal hospitals of the world, in order to obtain ideas for the Cincinnati building. He certainly has collected a vast fund of information relating to hospital construction. There is no space here to discuss at length the wealth of information given by Dr. Holmes. On the matter of ventilation he holds some very decided views. He is absolutely opposed to the plenum system of ventilation—that is, by downward draught, and stated that the magnificent maternity hospital erected by J. Pierpont Morgan on Sixteenth street and Second avenue, New York, did not use the elaborate plenum system of ventilation which had been installed, but used the primitive method of ventilating by means of the open window. Dr. Holmes showed on the screen specimens of hospitals, old and new, from almost all parts of the old and new worlds, and managed to convey to those present vivid ideas of what these institutions were like. Other papers read were "Hospital Management from a Visiting Surgeon's Standpoint," by Dr. Chipman of the Royal Victoria Hospital, Montreal; "The Treatment of Patients with Abnormal Mental Symptoms, and of Such Insane Cases as May Necessarily Require to Be Retained Temporarily in a General Hospital," by Dr. W. U. Barnhardt of the Central Islip Hospital for Insane, New York. A "Question Drawer" was conducted by Miss Louise Brent of the Hospital for Sick Children, Toronto.

In the afternoon the Insane Asylum at Long Point was visited.

The meeting was most successful from the social standpoint, as well as from the point of view of instruction. Much of the credit for these results must be given to the President, Mr. Webster, and to the indefatigable secretary, Dr. J. U. E. Browne.

FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE.

(From Our Regular Correspondent.)

MANILA, P. I., March 8, 1910.

THE first biennial meeting of the Far Eastern Association of Tropical Medicine held its opening session in the administration building of the new Philippine General Hospital on the afternoon of March 5, 1910, at 3 P. M.

Owing to the absence from the city of His Excellency, Governor-General Forbes, the foreign delegates and members were welcomed by the Hon. Gregorio Araneta, Secretary of Finance and Justice, on behalf of the Insular Government, and for the city of Manila by the mayor, Felix Roxas. The former in a short felicitous address, which he stated was the first he ever attempted in the English language, spoke of the value and stimulus the medical men, as well as the community in general, would receive from exchanging ideas and coming into contact

with so many illustrous exponents of tropical medicine from the different countries of the Eastern Hemisphere. He was followed by Dr. Paul Freer, the president of the Association, who chose for his subject "The Tropical Sunlight." He reached no definite conclusion, but pointed out a line of research on this subject which offered much promise. He did express the opinion, however, that from the evidence available it seemed most improbable that chemical action, and especially that of the actinic rays, was different in this latitude than that of Chicago, for instance. He also laid particular stress upon the high ionization of the air in Manila, the same amounting to 45 volts per hour during the day time, which was much higher than that observed in temperate climates.

The following countries were represented: *China*—Dr. Francis N. Goddard, Shaohsing; Dr. Henry S. Houghton, Wuhu; Dr. Mary Fulton, Canton. *New Zealand*—Dr. J. S. Purdy, Auckland. *Madras*—Major C. Donavan, I. M. S. *Hong Kong*—Dr. Francis Clark, Dr. John M. Atkinson. *India*—Sorab K. Engineer, Bombay; Major A. Hooton, I. M. S. *Straits Settlements*—Dr. Gilbert E. Brooke, Singapore. *Netherlands Indies*—Captain H. M. Neeb, Dr. J. de Haan. *Java*—Dr. W. T. de Vogel, Semarang. *Imperial German Government*—Dr. Staby, Tsingtau. *Federated Malay States*—Dr. H. Fraser, Kuala Lumpur. *Siam*—Dr. H. Campbell Highet. *Japan*—Dr. Gorosaku Shibayama. *Ceylon*—Dr. Aldo Castellani.

It will, perhaps, be remembered that this Association is the outgrowth of the Philippine Islands Medical Association and had its birth at the annual meeting of the latter two years ago at a time when the majority of the Oriental countries were represented by delegates. The Association had the support of the Philippine Government from the beginning, an appropriation being made to defray the expenses of the first meeting. Practically all the countries in the Eastern Hemisphere have given it official sanction by sending delegates to the first meeting, no less than eighteen being present.

The official opening was followed by a reception in the evening at the University Club. This function proved to be most popular and gave the delegates an opportunity to become acquainted with one another and with the local members as well as others of Manila.

Sunday, March 6, was taken up by a trip to Cavite to visit the United States Naval Hospital at Cañacao. A special steamer took a delegation over at 10.30 A. M., and returned at 3.30 P. M. This trip was most instructive, especially on account of the fact that the new hospital wards for the accommodation of two hundred patients, constructed with the view of making them suitable for the tropics, had just been completed. A new laboratory building and a new operating room have also just been added. After the visit of inspection was completed, Dr. Stitt, the medical officer in charge of the hospital, tendered the delegates a lunch.

It is proposed to have the scientific meetings of the Association begin at 9 o'clock each day and hold only one session, which will probably end about 1 o'clock. In this way the delegates will be given an opportunity in the afternoons to visit such points of medical interest as they may desire, and also will avoid the hot hours of the day for scientific work. The sessions to take place in the administration building of the Philippine General Hospital every day until Saturday, March 12, at which time the Association will transfer its place of meeting to Baguio, the summer capital, where a special meeting upon climate, hygiene, and sanitation and kindred subjects will be held. The trip to Baguio will afford the delegates an opportunity to make a 130-mile railway journey through the heart of the Island of Luzon, and a 20-mile automobile journey over the famous Benguet highway, which winds its tortuous course up a narrow, rocky cañon to a height of 5,000 feet above sea level, and furnishes what is probably one of the finest short scenic automobile trips in the world.

From a scientific standpoint, the meeting starts out with much promise, because it will probably be at this meeting that the etiology of beriberi will be placed upon a definite and firm basis. Dr. Henry Fraser, who has been engaged in this work in the Straits Settlements, will be present to read a paper. Professor Aron of the Philippine Medical School coincidentally has reached almost identical results working along independent lines, which, of course, gives considerable additional hope that the etiology of this disease will be firmly fixed.

The officers for the current year are: *President,* Paul C. Freer; *General Secretary-Treasurer,* Francis Clark, Hongkong; *Secretary-Treasurer,* Samuel C. Gurney, Manila, Philippine Islands.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 7, 1910.

Pain Relieved by Manual Therapy.—E. C. Thompson says that pain may arise in any structure of the body and may be classified roughly into inflammatory and non-inflammatory, and then again may be subdivided into functional, vascular, articular, nervous, and mechanical in various combinations. He refers to manual therapy among the ancients, and mentions its value in sprains, bruises, fractures, acute multiple arthritis, gonorrheal arthritis, myalgia and lumbago, neuritis, sciatica, neurasthenia, frost bite, intestinal colic, flat foot, cramps, erythema nodosum, and locomotor ataxia. The chief work falls on the thumb and finger tips, the palmar surface of the fingers, and the thenar and hypothenar eminences. The movements (always concentric) vary from the lightest effleurage to the most thorough petrissage and tapotement, followed frequently by active, passive, assistive, and resistive movements, or various combinations. All these manipulations should never cause any pain in their application, but should be followed by relief of pain or tension, and a general feeling of lightness and well being. On the other hand, too rough or violent manipulation will defeat the object in view and cause increased pain, bruising, and general aggravation of existing symptoms.

Tetanus; Seat of Infection in the Uterus.—A case is reported by F. W. Johnson of a woman who had aborted eight days previously and was living in filthy surroundings. Following the abortion there was profuse flowing for which, on two occasions, the vagina had been packed with sterile gauze. Soon rigidity of the neck muscles appeared with slowly increasing contractions, clonic, and frequent tonic spasms. During the next night opisthotonos came on and later general convulsions, in a third of which she died. Autopsy was refused. On the morning of the day of death, the uterus was curetted. From these curettings tetanus bacilli were grown.

Uterine Constriction Bands Complicating Labor.—J. C. Hubbard refers to Bandl's ring versus the constriction or retraction ring. Authorities have described the latter as due to the circular fibers alone and most common around the neck of the child, although it may occur in any horizontal zone of the uterus. In the discussion of the origin of the band weight is laid on the character of the cells lining the lower uterine segment of the uterus. If they are of the type of the cervical cells, then the band becomes Bandl's ring; if decidual in character the ring is then a constriction ring. In the author's mind it makes no clinical difference by what name the band is called when it or the accompanying conditions prevents the proper progress of the labor. It is more frequently found in cases in which the presenting part has stopped while the latter is still high in spite of apparently good uterine action. Even with the patient under ether ready for delivery, the band might be overlooked unless the interior of the lower portion of the uterus was explored. Among the causes which produce bands the books mention mechanical obstructions to labor. The uterine muscle tries ineffectually to force the baby past this obstruction and finally becomes completely or in part tonically contracted. The band is thus a secondary result of the delayed labor. The author believes that in many cases at least the reverse is true, for the band, to his mind, develops first through irregularity of the action of the uterine muscle and thus directly prevents progress. The occurrence of the ring has seemed to him to be more common in private than in hospital practice, and he has wondered whether the condition, as he now sees it in the "over-civilized" young woman, was only a tendency to ring formation which might correct itself if the patient were allowed to have the long labor formerly so common in hospital practice. Personally he does not feel that this is true and he feels that his cases would have gone from bad to worse if left alone. The most probable explanation seems to him to be the generally highly strung make-up of his private patients. In them the uterus does not pass through its various stages in a more or less mechanical manner as in an animal, but takes part in the over-development of the nervous system of the woman, and after a short time begins to act irregularly with the result of an early ring formation. The presence of a ring is an absolute indication for delivery. The earlier one operates in such cases the less the mortality. The latter should be nil. Several clinical histories illustrate the points made by the author.

New York Medical Journal, April 9, 1910.

Relationship Between Rectal Diseases and Those of the Female Pelvic Organs.—J. P. Tuttle says that disease of the rectum and female pelvic organs may affect functionally or sympathetically any portion of the body. The propinquity and anatomical relationship between these parts would naturally lead one to anticipate a close relationship in their pathological affections. Traumatisms of one are likely to invade the other. Inflammations from one are liable to extend to the other directly or through vascular connection. The chief symptoms to which attention is called are pelvic and sacral pains, irregularity of function, inguinal or iliac tenderness, pains shooting down the legs, reflex pains, digestive disturbances, and mental and nervous affections. Many of the pains from which women suffer are due neither to rectal nor pelvic lesions, but to strain, inflammation, or rheumatism of sacroiliac joints. Removal of hemorrhoids or the stretching of an anal fissure may relieve pain in the eye, constant headache, and facial neuralgia. Rectal conditions may cause dysuria, vaginismus, dysmenorrhea, stricture, fissure, cryptitis, or inflammation of the crypts of Morgagni. Pain shooting down the legs occurs in both rectal and pelvic lesions. The leg in which the pain is situated is of no significance as to the seat of lesion. Left leg pain is not of diagnostic significance as to the rectum being involved. Adhesions of the gut through inflammation of the uterus and its appendages are common causes of interference with the intestinal functions. It is a common assumption that tenderness or pain in the iliac regions made worse by walking, deep pressure, or palpation through the vagina is due to tubal, uterine, or ovarian diseases, but such pain and tenderness are frequently associated with inflammation of the sigmoid, or angulations of the bowel, with a fecal accumulation above, and pressure upon the female pelvic organs. These same conditions have been found to account for the dragging pains associated with and often falsely attributed to "falling of the womb."

A Case of Banti's Disease.—The report of the case is made by O. Lerch, whose patient was a woman of thirty-two years, who was first seen by him thirteen years after her first symptoms had begun. He says of the case that in a healthy individual after an infectious disease, that may or may not have been malaria, no history of typical malarial paroxysms, no blood examination was made. The disease was contracted in the settled portion of the city, with paved streets and good drainage. Continuous general malaise and ailing pointing toward a general intoxication continued for two years, when enlargement of the spleen, large liver, and ascitic fluid were first noticed. As two years had passed after onset of the disease before the changes in spleen and liver were noticed, it was impossible to say at this time whether the changes in the spleen had been primary or whether they had been simultaneous with the liver changes. It seemed rather more probable that the latter had been the case. The condition was marked by its chronicity and its remissions. The patient's weight had not varied for ten years. She was of rather slight build. Face, back of hands, and forearms were covered with large, bronzed spots, finger nails pale, also lips and other mucous membranes. The sclerae were slightly icteric, the tongue coated, the teeth healthy and in good condition. The neck showed bronzed spots on both sides. The general appearance was cachectic and waxy. The arteries were easily compressible; pulse 80, regular; heart borders normal, hemic murmur. The lungs were normal. The abdomen was distended with gas; no ascitic fluid could be made out. The liver measured 4½ inches in the right mammary line, its border was palpable, smooth, and hard. The spleen was enormously enlarged and reached below and beyond the umbilicus, the borders of the organ were smooth and it had preserved its form. The urine was normal in every respect. The only abnormal feature of the blood was a diminution of the red cells, 4,000,000, and its low percentage of hemoglobin, 60.

Journal of the American Medical Association, April 9, 1910.

Iliopsoas Tumor.—T. S. Cullen gives the history of a case in which he was called in consultation on account of a tumor, the patient complaining that every time he put his weight on his left leg something slipped in his hip. There was a firm oval mass, 8 x 10 cm., occupying the left iliac fossa and extending beyond the median line. This was continuous with a smaller mass which passed below Poupart's ligament and extended to the left of the hip joint anteriorly. Operation revealed a cystic tumor containing a viscid yellowish fluid in which five large irregularly cartilaginous masses floated free and a sixth was found fastened down beneath Poupart's ligament. The pelvic sac was dissected free and cut away and the wound healed up, leaving some discomfort in the leg and a slight lameness but no pain in the hip joint. The walls of the sac were fibrous tissue containing cartilaginous and bony masses, some of them being quite conspicuous. The origin of such tumors is discussed. They develop from the iliopsoas bursa, one of the largest, if not the largest, in the body. The subject has been well discussed by Zuelzer and the cases collected by him are reviewed. Zuelzer points out that these growths may be of various sizes and may extend under Poupart's ligament half way down the thigh In some cases they may be so tense or thick in the walls as to suggest a solid tumor. The pain is what might be expected from pressure on the crural nerve under which the growth develops. The leg is held in position causing the least tension on this nerve, *i. e.* in abduction, outer rotation, and slight flexion of the hip. As a rule, the hip joint is normal and there is no shortening. The majority of these cases follow injury, though syphilis and rheumatism are also supposed to be contributing factors. Cases similar to the one reported require complete removal of the sac and under no circumstances should irritants be injected. The surgeon cannot usually determine definitely before operation whether these bursæ communicate with the joint or not.

Surgery of the Hypophysis.—J. Montgomery West analyzes the different methods of approaching the hypophysis and points out how the experience of the rhinologist may be of service to surgeons in reaching this organ. He proposes a surgical method following a transnasal route diagonally through the nose, roughly parallel to Zuckerkandl's line, to the sphenoid sinus, removing as much as is necessary of the turbinates, the entire anterior walls of the sphenoid sinuses, a quadrilateral piece from the nasal septum, including the septum sphenoidale and finally attacking the sella turcica. This takes advantage of the space afforded by the natural nasal passages and permits the sella turcica to be opened up with the least possible destruction of tissue. He thinks, moreover, that the greater part of this operation can be done under local anesthesia. With the use of adrenalin the nasal passages can be made so patent that in most cases the anterior walls of the sphenoid sinuses can be seen over a considerable area by inspection through the nostril. The nasal surgeons have developed the technique already to the point of opening up the sphenoid sinuses and it seems an easy step to cross these and attack the sella turcica. He thinks this method would be specially available for partial removal of the lower and posterior part of the hypophysis and also would be better as causing less disfigurement.

Fracture of Long Bones in Children.—W. P. Coues calls attention to the importance of a class of fractures of long bones in children which may pass unrecognized without the use of the *x*-ray. The subperiosteal fractures may be lacking in crepitus, abnormal mobility and swelling and ecchymosis may be absent. Careful examination, however, may give valuable information. There is localized tenderness along the site of fracture which is increased by the classic test of lateral traction above and below the site. In long fissures or linear fractures, rotation will always give the most pain. Several cases are reported. Treatment of these cases should be the simplest that is adequate to maintain fixation until solid union is obtained and a permanent anatomical and functional result may be expected. Rough manipulation and forcible testing for crepitus should be avoided in diagnosis, and an anesthetic is not required. These children often complain of pain and trouble at points distant from the fracture and the *x*-ray examination should not be confined to the part complained of but should include the neighboring long bones as well.

Trachelorrhaphy.—W. L. Wallace, after referring to the frequent unsatisfactory results of trachelorrhaphy and the tendency to substitute for it amputation of the cervix, says that the trouble is that the site of the repair is apt to be so thin that it cannot possibly withstand the strain of another labor. The poor result, he thinks, is brought about by the faulty method of through and through stitching by which the side of the cervix is compressed to thinness, the ligature drawing so tight. A repair of the cervix he thinks should follow the method of layer suture so successfully used in closing the abdomen. He uses a continuous suture in two layers, the deeper suture being carried deeply back and forth into the muscular layer of the anterior and posterior lips, and pulling up each stitch as the operation proceeds broadly approximating the depths of the wound. Then it is carried up to the edges after hav-

ing crossed the tear and the superficial stitch is taken continuously by running back the same continuous suture coming out opposite the point of starting with the deeper one, where the two ends are tied together. He uses No. 1 chromic catgut, no tension being required. The method is very simple and rapid and the result has been very satisfactory in his experience. The article is illustrated.

Unusual Epileptic Aura.—Alfred Gordon reports the case of a boy of 12, suffering with essential epilepsy at irregular intervals since his second year, who for about forty-eight hours before an attack was constantly going about kissing everybody he met, the kissing being sometimes replaced by laughing and sometimes by slapping or striking. During all this time he was apparently conscious and realized what he was about. After forty hours or more of this he had the regular epileptic attack. Gordon questions the conscious mental state of the boy during this prodromal period and compares it to the maniacal period of manic depressive insanity.

The Lancet, April 2, 1910.

The Failure of Nerve Anastomosis in Infantile Palsy.—R. W. Murray says that but few instances of a really satisfactory nerve anastomosis for infantile palsy have been published. The cause of failure may be (1) the choosing of an inappropriate time for operation, (2) a faulty surgical technique and (3) the fact that physiological reasons do not permit of recovery. He considers that no operation should be contemplated unless for six months from the onset of the disease assiduous treatment has been directed to the palsied muscles to improve their nutrition and to assist the return of power by adequate postural support, and further, that at the end of this time faradic irritability must be absent, although a strong current is used when the patient is anesthetized. Experience shows that it is the deltoid which in all acute peripheral palsies of the upper arm shows the least response to the methods of nature and art and some means of restoring the abductive power of the arm is urgently required. Possibly the circumflex may be anastomosed to another nerve. As regards the technique in all cases the paralyzed nerve was completely divided. In three instances the peripheral end of the nerve was engrafted into a longitudinal slit made in the sound nerve. In two cases an end-to-end anastomosis was made. In one of these the divided external popliteal was joined to a flap raised from the sound internal popliteal nerve; in the other case the spinal accessory nerve was completely severed and joined to the divided fifth cord of the brachial plexus. Sutures were of very fine silk. The nerves were handled as little as possible, and the sutures passed with as little bruising as possible. Healing was normal in every case. In the experience of Robert Jones and the author, of 6 cases of obstetrical palsy 2 completely and 3 partially recovered, and of 4 cases of spontaneous neuritis, 3 completely recovered. In regard to physiological considerations, not only are the ventral cornual cells affected but possibly also the white tracts and the piamater. The clinical evidence that we are using a functioning nerve for the purpose of grafting is, of course, the presence of voluntary power and of faradic excitability in the muscles supplied by it, but the nature of the pathological lesion suggests that though these signs are present, yet even in the segment of the spinal cord from which the functioning nerve takes origin, recovery may be incomplete. Even three years may not be too long to afford evidence of complete recovery. In cases operated on from 8 to 14 months elapsed between the onset of the disease and the time of operation. Five illustrative cases are summarized.

An Anatomical Inquiry into the Pathway of Tuberculous Infection.—F. W. Jones believes that the absorbent system is the pathway for tuberculous infection and that bacilli may reach the lungs from the lumen of the alimentary canal without leaving any trace of their passage through its walls. The relation of the lymphatics of the posterior mediastinum, the thoracic and right lymphatic duct when compared with the common sites of tuberculous disease assume a new significance, for unless it is merely a striking coincidence the facts point clearly to these channels as the route of infection in lung and spinal tuberculosis. The thoracic duct is most intimately related to the spinal column from the sixth dorsal to the second lumbar vertebræ, the bodies of which are most subject to tuberculous infection. The position of the first appearance of caries upon the bodies of the vertebræ is highly suggestive of an infection from some structure lying on the front of the center, and in addition is the fact that caries at times commence from many centers often situated on different vertebræ and unconnected with each other. The structure most intimately related to the lungs or the site of election in phthisis is the lymphatic channel passing upwards and forwards over the pleura to join the subclavian veins. In this situation the thoracic duct or the right lymphatic duct lies directly on the pleura and in more intimate anatomical relation to it than any other structure in the thorax or neck. Regarding primary tuberculous disease of the thoracic duct we know but little. In one case of tuberculous disease of the lung, there was a firm adhesion between the diseased lung, diseased pleura, and diseased duct, a condition strongly suggestive of an invasion of the lung from a primarily infected duct. This would seem to bear out the frequent observation that a pleurisy is often the first premonitory origin of a phthisis. In the absence of more definite knowledge about the lymphatic system, these facts appear only suggestive, but they would appear to point to the fact that with advancing age the abdominal lymphatics become more constricted and the lymph circulation becomes more centered on the thoracic ducts. This theory offers a ready explanation for the different sites of infection of tuberculosis in children and in adults. If the mesenteric lymphatic would carry such substances as China ink (and tubercle bacilli) in children, the onset of tuberculous peritonitis is not difficult of explanation, and if the lymphatics of the diaphragm readily carry infection to the thorax in children, the basal phthisis is easily explained.

Wassermann's Reaction from a Practical Point of View.—J. E. R. McDonough says that in the primary stage of syphilis a positive result by the serum test cannot be obtained in more than 40 per cent. of all cases, and a positive diagnosis can be reached only by finding the *Spirocheta pallida*. The secretion from the sore must be examined by means of a dark ground illumination. It is wise to place no reliance upon a negative Wassermann in the primary stage. In the secondary stage a positive result occurs in 85 per cent. of all cases, alike when an eruption is present, when no manifestations of the lesion exists at the time, and when the patient is undergoing treatment. When there is a rash and the patient has had no mercury 97 per cent. of the cases are positive. When no sign is present 80 per cent. are positive. Such cases should receive treatment at once. The other 20 per cent. may be negative. (1) Because the virus has disappeared or is dormant and there is no specific antibody in the serum, (2) because the patient is taking mercury, or (3) because the patient forms one of the 3 per cent. who in any case give a negative reaction. In the tertiary stage 70 per cent. give a positive result. The following suggestions are made: (1) When a man infects his wife both should be rigorously treated and the woman should be retreated during each pregnancy. 2. (*a*) A syphilitic woman should be treated during the whole nine months of her pregnancy; (*b*) an apparently healthy woman whose blood gives a positive reaction should be so treated during each pregnancy. 3. (*a*) A syphilitic child should be suckled only by its mother, never by a wet nurse; (*b*) an apparently healthy child, either of whose parents has had syphilis, should be suckled only by its mother; (*c*) should such an apparently healthy child react positively to Wassermann's test, it should receive antisyphilitic treatment. A positive reaction can be obtained in a congenital syphilitic on the day of birth. A congenital syphilitic is peculiar in that mercury has but little influence in converting a positive into a negative reaction. In candidates for life insurance, a positive reaction should disqualify the risk even though years may have elapsed since the original infection for a positive result indicates some visceral lesion which will ultimately shorten life. On the other hand, a candidate may be accepted who, having completed a two years' course of treatment, shows a negative reaction on being tested at intervals of three, six, and nine months after such a course.

A Case of Tetanus Treated with Subcutaneous Injections of Magnesium Sulphate; Recovery.—A man of 21 years of age came under the care of P. Paterson three weeks after he had received a small scalp wound, which promptly healed and left no visible scar. Six days before being seen the symptoms commenced with pain and stiffness in the abdominal walls and back, gradually going on to full tetanus. Next day he received an injection of 10 c.c. of a 10 per cent. sterile solution of magnesium sulphate, which in two days led to great improvement, but he then relapsed. The injections had been given every four hours day and night, causing much pain. The severity of the spasms being serious the quantity of solution was gradually doubled and the interval between spasms gradually

became prolonged. The day after the treatment was stopped an erythematous rash appeared, spreading over the entire body. The patient recovered and left the hospital five weeks after admission. Relaxation of the muscles was a gradual process interrupted by a series of long drawn-out, painless, and ill-defined waves of tonic contractions mild in degree. During the treatment the patient took from 8 to 10 pints of fluid food and water. Urine was not increased, but he lay soaked in sweat. The author thinks the injection pains could be overcome by using larger quantities of a weaker solution.

British Medical Journal, April 2, 1910.

Some Idiopathic Cases of the Skin Which May Simulate Syphilis.—Commenting on the difficulty of differential diagnosis, P. S. Abraham says that the imitation is rarely correct, but there is very frequently a mixing of the types of two or more in one. He pays special attention to psoriasis, pityriasis rosea, impetigo, ecthyma, rodent ulcer, mycosis fungoides, pemphigus vegetans, and dermatitis herpetiformis. In his experience no idiopathic disease of the skin is more frequently mistaken for syphilis than is pityriasis herpetiformis, but in the former there is no accompanying adenitis, no throat trouble, or other sign of syphilis, although the patient may have been otherwise out of sorts and have had some digestive disturbance. The cases supposed to be dermatitis herpetiformis are rather instances of a syphilitic disease simulating the former than the reverse. In all doubtful cases the modern methods of the serum reaction and the discovery of the *Spirocheta pallida* will generally enable us to solve all matters of doubt.

Double Loop Hernia.—J. A. C. Macewen reports one case of a left femoral hernia in which only one loop was strangulated. The patient was a miner of 66 years, with abdominal symptoms lasting five days. In the left groin there was a large mass suggesting a solid tumor but there was a tympanitic area over one end and a hernia was suggested. Incision revealed a double loop, one part being evidently of recent origin, and the other evidently of long standing. The recent part was ligated and cut off, while the old part was reduced *en masse*. One theory put forth as to the origin of these W herniæ is that a single large loop of bowel comes down into the sac and that subsequently the central portion of the loop slips back into the abdomen, thus forming the W. In favor of this theory is the generally large size of such herniæ and the fact that often the connecting loop of bowel, notwithstanding its position in the bowel, is damaged. This particular case does not, in the author's opinion, bear out this view. The entire absence of pressure symptoms upon the old portion of the lesion is probably to be accounted for by its very long pressure in the sac, the bowel having become thickened and easily capable of resisting any pressure upon it. The author refers to Lauenstein's suggestions as to diagnosis of this double loop hernia as follows: (1) the size of the hernia, which is generally scrotal, right-sided, and of long duration, (2) signs depending on the condition of the middle loop, such as marked asymmetry of the lower half of the abdomen where the loop is much distended, furrowing of the scrotal tumor indicating the line of separation between the two loops, which may further yield different percussion signs, one of fluid and the other of gas; (3) effusion of fluid into the abdominal cavity. In the present instance the size and long duration of the condition were the only features present of those suggested, the tumor being uniform in contour, owing probably to its thick envelopes as compared with those of a scrotal hernia, and the abdomen uniform and free from effusion, owing to one loop only being strangulated, and there being thus no affection of the middle loop. The author's case made a good recovery.

Amputation for Diabetic Gangrene.—A. E. Johnson reports the case of a woman of 62 years with gangrene of the left leg. Under localized anesthesia the anterior crural and great sciatic nerves were exposed, blocked off with a solution of novocaine and the incisions closed. General anesthesia was then given with nitrous oxide gas and oxygen. The patient made a good recovery from operation. Dram doses of bicarbonate of soda were given as a prophylactic against the onset of coma. Some seven weeks were required for the healing at the site of insertion of the drainage tube. The limb was amputated at the junction of the middle and lower thirds of the thigh. The patient remained well about three months and then began to fail, dying of coma some seven months after the operation was performed. The author strongly commends the local anesthesia in these cases. He says that the dangers of sepsis in diabetic cases lie in the special liability of such cases to septic conditions, the poor nourishment of the tissues owing to endarteritis, the interference with the proper nerve supply owing to the neuritis and the presence of free sugar in the blood and tissues forming a good breeding ground for microorganisms. These dangers require special precautions apart from those called for in all surgical procedures. The use of a tourniquet should be avoided if possible, and all tissues tenderly handled. Drainage is a serious question. At the best the tissues heal very slowly, but if there is exudation in the tissues, a very small drainage tube had best be used and a suture should be inserted for tying when the tube is removed.

Rupture of Both Quadriceps Extensor Cruris Tendons.—A case is reported by R. Kelly, whose patient, aged 60, a coal salesman, slipped while carrying a bag of coals and fell forward, losing all power in his right leg. He tried to get up by putting his left beneath him; this also gave way, so that both legs were completely powerless beneath the knee. He was carried home and both quadriceps tendons were found ruptured, leaving large gaps above the patellæ. Horseshoe-shaped strips of plaster were applied to bring down the ruptured ends of the tendons, and long splints applied to both legs. The legs were kept rigid for six weeks, when splints and plaster were removed and passive movement and massage applied for four weeks more. The man made an excellent recovery and resumed work twenty-four weeks from the time of the accident.

Münchener medizinische Wochenschrift, March 22, 1910.

The Disinfection of the Skin and the Treatment of Wounds by Iodine Vapor.—Jungengel discusses the use of tincture of iodine in the disinfection of the skin and wounds and then points out the advantages of using iodine vapor instead of the tincture. He describes an apparatus, invented by himself, to produce the iodine vapor. It has the following points in its favor: It is easily used, cleaned, and sterilized. The air which is used to mix with the iodine is made bacteria free. In spite of the great heat needed to vaporize the iodine (this boils at 356° F.), the air is cooled sufficiently to prevent the burning of the skin. The dose of iodine can be regulated. The iodine vapor is used in a very finely divided state, no droplets being produced. The author then describes his experience in skin disinfection and wound treatment by means of the apparatus. It is of especial value as applied to large abscesses, fistulæ, phlegmona, and bone cavities. He has used it in 91 operations and in no case has injury of the wound resulted. Appendectomy and herniotomy wounds healed very rapidly.

Perforated Gastric Ulcer in an Hour-Glass Stomach.—Georg Hirschel gives a report of such a case in a saleswoman twenty-five years of age. The patient was admitted in collapse. The history was negative except for occasional slight discomfort after meals. The acute attack followed immediately after a severe blow on the abdomen. The patient was operated upon six and a half hours after the accident. The operation revealed a very marked degree of hour-glass stomach, the opening between the two halves being no larger than a lead pencil. The perforation was located upon this constriction. Owing to the narrowness of this portion of the stomach it was impossible to sew up the ulcer without completely blocking the passage. The two halves of the stomach were, therefore, divided and each closed separately. A gastroenterostomy was then done to the cardiac portion of the stomach, and the patient made an uneventful recovery.

Mechanism of the Biological Action of the Röntgen Rays.—Vittorio Maragliano says that the *x*-rays exercise their action on the living cells and tissues on account of the amount of the rays that are absorbed, and of those that simply pass through them. The author bases this assertion on his experiments on animals and on physical and biological facts. The photographic action of the rays is not in direct relation with the rays absorbed by sensitive emulsion. They have a deep as well as a superficial action. Some of the deeper organs are more opaque and absorb a larger amount of rays and react before the superficial ones. The filtered rays act less energetically than the unfiltered ones in animals. These reasons show that the total amount of irradiation which passes through the tissues acts on them, and not solely the rays that are absorbed.—*Giornale di Electricita Medica.*

Book Reviews.

TEXT BOOK OF MEDICAL AND PHARMACEUTICAL CHEMISTRY. By ELIAS H. BARTLEY, B.S., M.D., Ph.G., Professor of Chemistry, Toxicology, and Pediatrics in Long Island College Hospital; late Dean and Professor of Organic Chemistry in the Brooklyn College of Pharmacy; late Consulting Chemist to the Department of Health of the City of Brooklyn, etc. Seventh Revised Edition. With Ninety Illustrations. Philadelphia: P. Blakiston's Son & Co., 1909.

IN this revision there are but few changes, most of them being found in the sections on Organic Chemistry and Physiological Chemistry. The part devoted to the proteins has been rewritten and made to conform with the classification and nomenclature recommended by the American Physiological Society and the Society of Biological Chemists. We note that the nomenclature in general does not follow that adopted by the American Association for the Advancement of Science. The size of the volume is not materially increased, and the book will continue to be popular, or at least as popular as a book on chemistry is likely to be with medical students.

A TEXT-BOOK OF THE PRACTICE OF MEDICINE. By JAMES M. ANDERS, M.D., Ph.D., LL.D., Professor of the Theory and Practice of Medicine and of Clinical Medicine, Medico-Chirurgical College, Philadelphia. Ninth Revised Edition. Philadelphia and London: W. B. Saunders Company, 1909.

THIS edition of a well known work on practice is, as claimed, a thorough revision of its predecessor of two years ago. In even so short a time the advances in the subjects concerned are such that "new and rewritten" matter must be a leading feature in such a production, and here we find it so. The management of cerebrospinal fever would not be considered complete now without consideration of lumbar puncture, for at least diagnosis, and this raises the hope that the work done toward a curative serum, for injection while tapping, has not been in vain. In the epidemics of meningitis in 1905 the use of diphtheria antitoxin was suggested, but disappointment followed. Now we have the encouraging work of Wassermann and of Flexner on serums, and consideration of their value is found here. Under erysipelas and pernicious anemia mention is made of new treatment. Under Stokes-Adams disease the differential diagnosis includes not only bradycardia and arrhythmia, but also recurring extra-systole. Cerebral hemorrhage includes ventricular, pontine, and cerebellar, also serous apoplexy, with tables on differential diagnosis of hemorrhage, thrombosis, and embolism. Diseases of the nervous system receive considerable attention in pathology and diagnosis, as chronic poliomyelitis, progressive muscular atrophy, chronic myelitis, diseases of the optic nerve. Tropical diseases are given enlarged space, as present-day American problems give them increasing importance. The work is well arranged in divisions and subdivisions of sections, the few illustrations are good, and the plates, particularly on malaria and leukemia, are excellent, the latter deserving special mention.

MODERN SURGERY. General and Operative. By JOHN CHALMERS DA COSTA, M.D.; Professor of Surgery and Clinical Surgery in Jefferson Medical College; Surgeon to the Philadelphia General Hospital; Consulting Surgeon to St. Joseph's Hospital; Fellow of the American Surgical Association; Member of the American Philosophical Society; Membre de la Société Internationale de Chirurgie; Member of the Medical Reserve Corps, U. S. A. Philadelphia: W. B. Saunders Company, 1910.

THAT surgery is still progressing and that its triumphs are not all of the past is evidenced by a consideration of the extensive revision which this work has undergone to prepare it for this edition, appearing only three years after the fifth. Among these revisions and additions we find mention of the work of Carrel, Matas, and Murphy on arteriorrhaphy; Crile's arteriovenous anastomosis for effecting transfusion of blood; Brewer's tubes for transfusion; the use of Halsted's aluminum bands in the treatment of aneurysm; the operative treatment of recent fractures; Horsley's operation for chronic spinal meningitis; the use of positive and negative air pressure in intrathoracic surgery; Murphy method of treating acute peritonitis; Cushing's operation of decompression for brain tumors; Bier's intravenous local anesthesia; the parathyroid glandules; the intraglandular extirpation of goiter, which is favored by Halsted and the Mayos; the Lorenz treatment of hip disease by weight bearing and fixation; cystoscopy and catheterization of the ureters; gunshot wounds in war; Bier's treatment of inflammation; Wright's views on inflammation; Rosenberger's method of diagnosticating tuberculosis by finding the bacilli in the blood; immunity with a sketch of antibodies, of opsonins, and of phagocytosis; bacterial vaccines; untoward effects of sera; tuberculin in diagnosis; fat embolism; erysipeloid; human glanders; Wassermann's reaction for syphilis; the serum diagnosis of cancer; tumors in general; syphilis; acute dilatation of the stomach, mesenteric cysts, congenital idiopathic dilatation of the colon, teratoids and dermoids of the sacrococcygeal region; gonorrhea; ankylosis; radium, electrical injuries, and the *x*-rays. The mere catalogue of these additions is sufficient to show that this work is in no danger of losing the position which it holds as one of the best of the one-volume treatise on surgery. We fear, however, it will not enjoy this distinction long, for if it continues to grow by accretion at the present rate, a division into two volumes will soon be necessary; this would be a convenience in a way, yet a disadvantage.

DISEASES OF THE STOMACH. A Manual for Practitioners and Students. By S. H. HABERSHON, M.A., M.D., F.R.C.P. With eight colored and eleven black-and-white plates. Chicago: Chicago Medical Book Company, 1909.

THIS little work is a concise and intelligible description of the diseases of the stomach, written especially for students and practitioners. It is authoritative, and is written chiefly from the clinical standpoint. There are valuable preliminary chapters on the anatomy and physiology of the stomach, nutrition and diet, examination of the stomach and of gastric contents, and on the symptoms of gastric disease. The author has availed himself of the researches and writings of all the acknowledged leaders in this subject, he has also brought to his task the extended experience of himself and of his father; and the result is a volume of unusual merit, whose practical value is far in excess of its size and price, and which the practitioner will find of more service than many of the larger and more pretentious works.

A PRACTICAL TREATISE ON OPHTHALMOLOGY. By L. WEBSTER FOX, M.D., L.L.D., Professor of Ophthalmology in the Medico-Chirurgical College; Ophthalmic Surgeon in the Medico-Chirurgical Hospital, Philadelphia, Pa.; Member of the Army Reserve Medical Corps, etc. Six colored plates and three hundred illustrations in text. New York and London: D. Appleton & Co., 1909.

THE character of the new issue of Dr. Fox's work on the eye is considerably changed from that of the edition of 1904. A new title has been adopted, the formulary and glossary have been omitted. The present volume is one of 807 pages. It is well printed and illustrated. Short chapters on "Embryology," "Anatomy," and "External Examination of the Eye" precede the chapters devoted to a consideration of the diseases of the eye, which last follow in logical order. A chapter each is devoted to "Ocular Manifestations of General Diseases" and "Ocular Manifestations of Nervous Diseases." Refraction and the extraocular muscles are then considered, followed by a chapter on "Laboratory Technique." Modern lines of thought and modern methods in ophthalmology are much in evidence. The rôle of microorganisms in the production of diseases of the eye is given its full importance. Operative procedures and operative technique are given *in extenso*, in fact, are rather the feature of the work. The operations peculiar to each part of the eye are treated in the chapter devoted to that particular part of the eye. There is little of theory in the work, the statements are positive and direct, bearing the imprint of the personality of the author. This treatise on the eye is excellent for the student and of value to all who are engaged in the study of the eye and its diseases.

A COMPEND OF HISTOLOGY. By HENRY ERDMANN RADASCH, M.S., M.D., Associate in Histology and Embryology, and Demonstrator of Visceral Anatomy in the Jefferson Medical College; Adjunct Professor of Physiology and Instructor in Histology in the Pennsylvania College of Dental Surgery. Second Edition, revised and enlarged with 107 illustrations. Philadelphia: P. Blakiston's Son & Company, 1909.

AMONG the changes in this new edition are some additions to the chapter on the circulatory system; the chapter on the nervous system has been rewritten; the chapter on the histology of the teeth has been enlarged and rewritten, and a new chapter has been added on the development of the face and teeth. The subject matter is up-to-date, and is presented in a clear and concise manner; and the book is more complete than most compends, and yet not so voluminous as a text-book.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 17, 1910.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

The Bacteriological Diagnosis of Venereal Diseases.—The Council referred the resolution requesting the Department of Health to undertake the bacteriological diagnosis of venereal diseases, gonorrhea, syphilis, and chancroids, to the Academy of Medicine. It was moved, seconded, and carried that the resolution be accepted. It is intended that a record of the age, sex, and social condition of such patients be kept, but that the identity of such individuals be not disclosed. When material is sent to the Department of Health, an examination will be made and the diagnosis returned to the physician, together with instructions regarding the care of such patients and the means of preventing the further spread of the disease.

An Interpretation of Some of Our Present-Day Social Phenomena.—DR. MAX G. SCHLAPP delivered this address. He said that all knew that during the past forty or fifty years unusual conditions were arising in society in general which he thought needed interpretation. There were some things about which sociologists had written a great deal and worried much, and one of the most important was the tremendous decline in the birth rate. There were other factors which very likely were due to the same causes, but which heretofore were not in any way associated with decline in the birth rate. Dr. Schlapp presented some charts which well illustrated the tremendous decline that had taken place during the last forty years in the birth rate. One chart showed that in France from the beginning of the Nineteenth Century the birth rate had fallen from 40 to below 20. In 1908 the births were 19,000 below the death rate. This fact required explaining. There were other factors to be considered and among these were the tremendous increase in insanity, and the increase in feeble-mindedness among children. The argument put forth by socialists that the birth rate declined with the bettering of the race was unquestionably a mistake. With a decline in the birth rate, there was an increase in insanity and an increase in feeble-minded conditions in children. This certainly spoke against the improvement of the race. There were other factors which were against the improvement of the race, such as the increase in certain nervous disorders, such as psychasthenia and neurasthenia. In Europe neurasthenia was referred to as the "American disease." Dr. Schlapp said that his interest in this subject was aroused by observing rather unusual conditions among a large number of female patients treated at the Presbyterian Hospital and other institutions. He had occasion to see a great many young women who worked in factories and offices, and other places out of their homes. The symptoms these people showed were a tremendous nervous condition, neurasthenia and the accompanying symptoms, psychasthenia and, in addition, there was a decrease or stopping of the menstrual flow. The question arose, what caused this partial or complete loss of menstruation when, among these patients, there was no other disease which caused this condition, such as acromegaly, myxedema, or other known debilitating diseases in which one found loss of menstruation? He came across these conditions in society as well. Dr. Schlapp believed that the answer was this—that Nature was beginning to avenge herself for the digression that had taken place in her laws. In order to explain this, one must go back and trace the sex from the earliest living organism. In the lower organisms there were conditions which pointed to a distinct sex. There were life processes in cellular organisms, and these life processes were three in number, the nutritive, the formative, and the functional activities; these represented the three processes that existed in living tissues. Nutrition supplied a limited amount of energy to the cells; this limited amount of energy was used up by the formative and functional activities. If either one of the activities increased, it must do so at the expense of the other. If either one of them used all the energy, there was none left for the other activity; hence, the other activity disappeared entirely. To illustrate this, he took one of the most highly specialized cells of the body, the ganglion cells of the nervous system. The formative activity was entirely lost in the adult individual. In the lowest organisms, such as the plant life or algæ, this condition was clearly shown; they reproduced and formed new organisms. But they must conjugate in order to be able to reproduce. There was a cycle in the lowest form of algæ termed the cell cycle, and this was represented by three stages, the quiescent stage, in which the cells divided and reproduced; the active functional stage, in which the cell was not capable of reproduction, and the transgressional stage passing from the active to the quiescent stage when it was not able to reproduce again. In the highest of the lower organisms one came to the dimorphic types where two sex cells could be distinctly differentiated. In the higher types conjugation was necessary before reproduction took place, and here was the beginning of the sex cells; there was the active small cell (male) and the large quiescent cell (female). In the multicellular organisms there was found the active small male cell and the quiescent large female cell. The multicellular organisms were made up of a large number of primitive sex cells. Some of these organisms were capable of multiplying by a sexual reproduction; that was, the body cells in the lower organisms were capable, if in sufficient numbers, of reproducing similar organisms, and it was not necessary to make use of the real sex cells. This was called asexual reproduction, or budding. What did this mean? It meant that the body cells in the lowest organisms had not lost their formative activity to such an extent that they were not capable of reproducing new organisms; in other words, their functional activity had not developed sufficiently to crowd out their formative activity. As one went up the scale in the animal kingdom it was found that the body cells were becoming more and more specialized, and took on more and more the functional activity; as one went up the scale more and more it was found that their capacity for reproduction became less and less until the intervertebrates were reached where this power was entirely lost and they were not capable of reproducing new organisms from parts of the body. In the lower organisms they found individuals in which there were present both sex cells, and this was a primitive state of affairs; both sex cells were found in one individual, and such an individual was called a hermaphrodite. As one went higher up the conditions changed, and the male sex cells were found in one individual, and the female sex cells in another; such individuals were termed unisexual organisms. From this period on the conditions developed which were called the secondary sexual character; the body cells as a rule were characteristic of the original sex cells. The speaker demonstrated what his meaning was with charts of the lower organisms. As one went higher in the scale the vertebrates were reached, and here one found, as a rule, the male was larger than the female; in the invertebrates this was reversed. In the intervertebrates the largeness of the female was due to the storing up of the energy for the reproductive function. The smallness of the male was due to the fact that in these individuals the functional activity did not require large amounts of tissue to carry on its function as in the vertebrates. In the vertebrates the functional activities required such large organs to carry on the necessary functions, such as skeletons, the muscular system, etc., that the largeness of the male individual was due to these systems and the storing up of energy among females did

not require such a large body. Dr. Schlapp here considered the antagonisms occurring between growth, development, and expenditure. The antagonism between growth and genesis meant, as a rule, the large animals were not as prolific as the small animals, all things being equal. If one took an animal from the time of birth, the body must grow to a certain extent before sexuality began. Growth antagonized reproduction. The growth of the body took place by using up energy which reproduced body cells. The antagonism between development and genesis had reference to the higher states of animals; the human being, for instance, belonged to a higher state than did fishes. As one went up the biological scale fertility diminished. The antagonism between expenditure and genesis was the most important and it meant that where a person was very active, reproduction diminished, and *vice versa*. Dr. Schlapp asked, what had all this to do with the decrease in the birth rate, with the increase in insanity, and the increase in feeble-minded conditions in children and the activity of women. The present social movements, such as Christian Science, antivivisection, suffragettism, etc., were movements all more or less controlled by women. Christian science was a return to the ignorance of primitive man, in that certain races tried to remove disease by prayer. Personally he believed that most of the women who were actively engaged in the suffrage movement were sincere, but movements of this sort were unwisely carried out. Woman must be conservative with her energies, especially at certain periods of her life, from the period of menstruation to the beginning of the menopause and, above all, she should conserve the energy that belonged to her children. If she did not conserve this energy for her formative activity, the child would suffer. How suffer? It meant that the organism had a running equilibrium, and must adjust itself to the outside world. If the adjustment was grossly disturbed, the running equilibrium was necessarily disturbed also, and the functions within that individual were interfered with. In the body there were certain tissues which were producing substances that had a marked effect upon other tissues of the body and they could either inhibit functional activity or lower it. Such substances were, for instance, the internal secretions of the thyroid gland, the thymus, hypophysis cerebri, the sexual glands, etc. The sexual glands were not present only for the purpose of reproduction of sex cells, but they had another important function, producing substances in the body which influenced the individual. Secondary sexual characteristics were the results of the influence of these sex cells upon the organism, and this influence was not only psychical but physical. The beard on man was the result of an influence of this sort, as was the high-pitched voice of woman, with the small larynx as compared with man. These conditions were due to the substances produced by the sex cells. The psychical elements in both sexes were very marked; there was the marked differences between men and women, between boys and girls, most marked between the ages of fourteen and fifteen in girls. These things were very important, and were conditions which influenced the lives of individuals. How did a woman's activity influence these conditions? The birth rate curve showed a decrease in the birth rate. In England and Wales there was an increase in insanity; in 1862 there were 41,129 insane; in 1904, there were 119,829 insane. The increase in population was not in proportion to the increase of the insane. The same was true of feeble-minded conditions in children. How could they explain this by the functional activity of women? Industrials had developed far beyond other conditions in life, and life had been made more difficult, and had forced women into certain activities which before that time she was not able to do. The women were using up their energies, not of the body only, but of the nervous system, which ought to be stored up for reproduction. Excessive functional activities of woman caused her to use up the energy which she ought to store up for the catabolic crises which came on in connection with her reproductive activity: if, moreover, the functional activities used up all this energy then, when the catabolic crises appeared, she having no energy left for this condition, there will be a marked disturbance in the crises; then if conception took place, the child would suffer from a lack of nutrition. Again, if she used up the energy for her functional activities, there was not enough energy left to supply all her tissues in a normal way, and there would result disturbances in her running equilibrium. This would result in abnormal functionating of the various tissues of the body, particularly of certain glands which were connected with the reproductive life. What effect had this upon the offspring? They would inherit the same pathologically changed tissues and glands; such offspring would develop certain conditions later on which might lead to insanity, or might even inherit distinct feeble-minded conditions. Women were actively engaged in furthering movements and trying to bring women into active life and no doubt they were sincere. But the question was, were they doing the best thing for the race? Were they not bringing about conditions which would result in an inferior race in the future? The mother he considered the biological balance wheel; if she used too much of her energy in other activities than to her offspring something was going to happen and it was taking place now.

Dr. E. C. Spitzka believed that the penalty of woman's activities could be traced further back than did Dr. Schlapp, and that from the very start something had resulted in their detriment, not in any fatal way, but in a hampering way. With regard to the suffrage movement he said he was not quite convinced of the complete sincerity of its advocates; there was a lot of hysteria in it. Some person once said to him, "Pay no attention to them; they will die out; they only want to be scratched." There were advocates of this movement among the males as well; he did not call them hysterical, but he recognized them as paranoiacs. He believed the problem would work itself out. After all, they were the people, and they held the fort. They might discuss the question of suffrage, but he objected to anything that touched the ideals of the mother and wife. They should think more of the influence of these things on the future and he did not think they should allow their children and their children's children to be punished because of these fads. He called attention to a fact not well known, that in families with idiotic and defective children, in nine cases out of ten the birth had been preceded by a miscarriage; this was a fact that was not sufficiently well appreciated by the profession.

Dr. Carlos F. MacDonald said that he could not subscribe to one point in Dr. Schlapp's remarks, that was, the enormous increase in the number of cases of insanity. Undoubtedly there was a very large numerical increase in insanity among civilized countries, but the question whether the ratio of insanity to the same population increased so enormously was doubtful. There were several explanations for this apparent increase, which was in fact more apparent than real. The conception of insanity to-day was a great deal wider than it was twenty-five or thirty years ago, or even within the period mentioned by Dr. Schlapp. The registration of the insane had increased enormously and so a larger number appeared in the statistics. There were a great many conditions to-day recognized and classified and registered that formerly were not. There was an increase too in the confidence of the public and the conduct and management of institutions for the insane had led people to seek treatment for their friends. Again the better care and treatment of the insane to-day had materially increased the longevity of that class of patients. Dr. MacDonald did not think that if a very careful

investigation was made that it could be shown that there was a great material increase in the proportion of the insane people.

SECTION ON SURGERY.

Stated Meeting, Held March 4, 1910.

DR. CHARLES N. DOWD IN THE CHAIR.

Streptothrix Infection Complicating Tuberculosis of the Kidneys; Nephrotomy; Nephrectomy; Recovery.—Dr. EMILY DUNNING BARRINGER reported this case. The patient was an Italian, 45 years old, who had had four children. Her previous health had been good. The history of her present illness had extended over two years before she was admitted to the hospital. Her chief complaint had been backache, especially on the right side. She had been treated for nephritis and displaced kidney. When she was admitted to the hospital she was in poor condition, running an afternoon temperature of about 101°, pulse from 88 to 116. The right lung showed areas of dullness. The heart findings were negative. In the abdomen a mass in the right kidney region was found; it was very tender. The blood examination showed red blood cells, 3,980,000, leucocytes, 9,500, and hemoglobin, 75 per cent. The tuberculin test was positive. A cystoscopic examination failed to reveal anything on account of the clouding of the field due to the quantity of the pus present. The Luys separator was introduced and the urine from each ureter was collected. The left urine showed 13.5 grams per liter of urea, was normal in flow, while from the right ureter there issued 3.5 grams per liter of urea. Both specimens of urine were repeatedly examined for tubercle bacilli and none were found. Two guinea-pigs were inoculated with these urines and showed the presence of the streptothrix. The patient's condition became urgent, and nephrotomy was performed. A second cystoscopic examination was then possible, as the urine had cleared up. The Luys separator was again used and indigo-carmine injected. This was freely excreted from the left side in eight minutes; none was excreted from the right ureter. This was six weeks from the time of inoculation. The report was received that the guinea-pigs had both developed tuberculosis. A nephrectomy was then performed. The temperature rose from 101° after the operation; it then fell, and the patient made an uneventful recovery. The urine at the last examination was normal except for the presence of a trace of albumin.

Implantation of a Portion of the Tibia into a Defect of the Ulna.—Dr. HENRY H. JANEWAY presented a woman who, twelve years ago, sustained a severe wrench of the arm. At the end of two months a tumor developed in the forearm which gradually increased in size. Five years ago this tumor was removed, but within a short time there was a recurrence calling for two subsequent operations. Finally in November, 1908, a complete excision of the tumor was made with a resection of the involved ulna. The growth proved to be a chondrosarcoma. The defect in the ulna caused by the removal of this tumor was replaced by a portion of the crest of the tibia, five and a half inches in length; Radiographs were presented showing that the implanted portion of the tibia had been transformed into, or at least, resulted in a thickness of live bone firmly united at its two extremities with the remaining fragments of the ulna. The functional results and cosmetic effects were excellent, the woman even being able to do her own washing in the tubs, and within one month after the operation. In this instance the wound healed by primary intention. The replacement of bony structures by bone from the individual himself, autoplastic implantation, was not generally used, only about ten cases having been reported; but the implantation of bone from animals, heterogenous implantation, has been frequently attempted, but without uniformly satisfactory results.

The End Results of Prostatectomy.—Dr. CHARLES H. CHETWOOD read this paper. (See page 698.)

Suprapubic Prostatectomy in Two Stages: Remarks and Report of Final Results.—Dr. HOWARD LILIENTHAL said that in looking over his list of private patients he was able to find records of sixteen upon whom he had performed the operation of suprapubic prostatectomy in two stages. The average age of these patients was 71; the youngest was 52 years old and the oldest 77. All except one left the hospital either entirely healed or with a superficial granulating wound. He had been able to follow and note the final results in all except two of these cases; the remaining fourteen cases were all well so far as urination was concerned and all were sexually potent, most of them with increased potency. After operations by the suprapubic method without perineal drainage, he had never seen a case of impotency in an individual previously potent. He had, however, quite frequently noted an increase of power which was quite decided. In several instances a bacteriuria persisted for weeks or months after the operation, but it disappeared under long continued medication. For the past ten years Dr. Lilienthal had done all his prostatectomies by the two stage method and without a fatality. In the list of sixteen cases the longest interval between the two stages was twenty days, the shortest two days, the average being about eight days. He asked what was the use of taking additional risks simply because the patient appeared to be strong enough to withstand the added shock?

Ureteral Calculus Complicating Acute Prostatic Obstruction.—Dr. WALTER BRICKNER reported this case occurring in a man 53 years old. After a preliminary suprapubic cystotomy, the small stone descended from the upper to the lower end of the ureter. A second stage operation was performed, a transvesical ureterostomy and prostatectomy. An early healing followed, with a complete restoration of urinary function, with no residual urine, and with a preserved *potentia coeundi*.

The End Results of Prostatectomy.—Dr. J. BENTLEY SQUIER said that in his first hundred prostatectomies the perineal operation was done 71 times, the suprapubic operation 21 times; in his second hundred operations the figures were about reversed, and he had not been influenced merely by the difference in the ease in performing the two operations. Whatever operation was done, the ultimate result was largely dependent upon the care and attention to clearing up the existing cystitis and in leaving the urethra in a healthy condition. To obtain the maximum benefit many patients required months of local treatment. Whatever operation was done, the indication was definite—total removal of the prostate with no damage to the compressor urethræ muscle. A permanent postoperative incontinence of urine was dependent upon the condition in which the compressor urethræ muscle was left, and was more apt to follow the infrapubic than the suprapubic operation. Temporary incontinence of urine was common, and was due to the cystitis and the deep urethritis and the relaxed condition of the sphincter muscle following the operation; the details of treating this incontinence in order to make it only temporary started with obtaining asepsis of the bladder and urethra and ended with motor reeducation of the cut-off muscle. What he stated about incontinence was equally true in regard to persistent fistulæ, suprapubic or perineal. One form of retention of urine occurred from Nature's reparative efforts. During the contracture of the cavity left after prostatic removal, a flap of mucous membrane might become shoved up so as to act as a valve and obstruct the internal meatus against the outlet of urine. A second

form of retention was caused by post-operative cicatricial stenosis of the vesical neck. What were the end results of prostatectomy? There were some failures, some improvements, and many cures, but differing from the majority of other surgical work in this—they were, as a rule, dealing with those who had already run the race, and were tottering on the brink of eternity. Such being the case, they had to conserve their every resistance to combat the shock of surgical intervention. There should be quickness in operation to minimize the amount of anesthesia necessary, wisdom in dealing with the details of convalescence, and patience while restoring a diseased bladder to health; these were the requisites of success.

Dr. Hugh H. Young of Baltimore believed that the method of performing prostatectomy through a median perineal incision was unquestionably an effective one, and had many valuable points in its favor, but he believed, also, that all these operations should not be performed in the dark. It was indeed a very simple matter to do the operation without going through the triangular ligament or bulb or injuring the external sphincter by simply stripping back the levator ani muscle on each side of the transverse perineus; this gave an easy access to the urethra, back of the triangular ligament, back of the sphincter; with the preservation of the external sphincter there should never be a fistula. One reason for a prolonged temporary incontinence of urine he believed to be the leaving back of a lobule which prevented the closure of the internal sphincter. Among four hundred cases of prostatectomy he had had but two in which incontinence of urine occurred, and only one recto-urethral injury which persisted. With regard to the persistence of urethral fistula, in his list of four hundred cases, there were two which still persisted; both of these fistulæ were pin point in character. In most of these cases such a condition was of slight disturbance. With regard to sexual potency, Dr. Young said he could not claim that perineal prostatectomy was a restorer of sexual power that had been lost; among the four hundred cases there were but five in which, following the operation, there was a return of the sexual powers. Among the cases in which the sexual power was normal before the operation, 80 per cent. claimed that it was only slightly impaired, while 20 per cent. of those in whom erections were normal before operation, had lost this power since the operation. With regard to obstructions, 300 cases led a catheter life before the operation, and but three cases had to return to catheter life since the operation. There had been a few cases in which the residual urine had not entirely and absolutely disappeared. In two cases that he had recently seen, the cicatricial tissue at the prostatic orifice caused a definite amount of residual urine to collect behind it; when this was removed by a punch, perfect results followed. To carry any patient successfully through prostatectomy depended upon a careful study of each case. Among Dr. Young's four hundred cases there had occurred 13 deaths, and a study of these cases showed that there had been a large amount of residual urine, the catheter had not been employed before operation, and that the operation had been performed without preliminary drainage by catheter. Had preliminary treatment been employed in these cases, the mortality would have been much lowered. There were some patients with from 500 to 1000 and more cc. of residual urine, and these were the cases that urgently required the preliminary treatment, and particularly those cases in whom the catheter had never been used. Every case with symptoms of uremia should always have preliminary treatment. The bladder should never be allowed to become distended beyond 500 cc.; if the bladder was allowed to contain 800 or 900 cc. of urine, the urine would be backed up in the ureters to the kidneys, and such patients of course would not improve as rapidly. The use of pheno-sulph-naphthaline had been of service in determining the function of the kidneys, both as to the rapidity with which the urine was put out and as to quantities. This agent first appeared in the excretion in seven minutes; 40 per cent. of it was excreted in the first hour, and 85 per cent. in the first two hours. As he already stated there had been thirteen deaths among his four hundred cases, and many of these might have been saved if he had been as careful then as now. In his last one hundred and twenty-eight cases he had been successful in all. The suprapubic operation Dr. Young believed to be a dangerous operation, with complications which led to an increased mortality. He had had forty cases operated on by the suprapubic route, and a higher mortality than he had had by the perineal route. Dr. Young advocated the perineal route, because he could get better results by this approach to the prostate.

Dr. Charles L. Gibson said that the only operation he had done during the last six or seven years was perineal intraurethral enucleation of the prostate; and of his cases, three died, one from cerebral apoplexy one month after the operation, one two months after the operation, as the result of general debility and sepsis, and one from uremia. In general terms, however, his late results following prostatectomy were excellent. The question regarding incontinence of urine in these cases was important, and one should be careful not to handle the membranous urethra or the musculature too much. The question of sexual power was one that had not bothered him very much, for it was concerned with the physiology of old age. Dr. Gibson had not had any experience with permanent fistulæ, and, in his work, he had never injured the rectum. The operation he performed he believed in, but it should be performed only in selected cases. In the great majority of his cases there was not a great amount of residual urine. After his operation he had never had occasion to use the catheter.

Dr. Joseph Wiener said that he had never had a permanent fistula follow the suprapubic operation, but he had seen such a condition follow the perineal operation for prostatectomy. He fully agreed with Dr. Lilienthal's statement, that every patient who submitted to this operation who was potent before operation was potent after the operation; in fact, there were a large number of patients who were rendered more potent after than they were before the operation. With regard to incontinence of urine, Dr. Wiener stated that, following the suprapubic operation, he had never seen a case which was permanent. He had seen, however, slight cases of incontinence for two, three, or four months following the suprapubic operation, which showed itself after coughing, sneezing, or some sudden strain, but he had never had a case of permanent incontinence after the suprapubic operation, and seldom did he see it following the perineal operation. Stricture of the urethra could be prevented in every case by attention to the proper technique; one should never get a stricture of the urethra after the suprapubic operation, and seldom get it after the perineal operation. Rectovesical fistulæ should never develop after the suprapubic operation. The formation of calculi occurred more frequently than the readers of the papers believed, and Dr. Wiener had seen them form in a few cases, and they were almost invariably phosphatic stones; these phosphatic stones formed in alkaline urine and, therefore, they could be prevented by keeping the urine neutral or slightly acid. These patients should be kept under observation for at least one year after the operation. He could not condemn severely enough the use of the galvano-cautery operation. If there had been any improvement in the technique in prostatic work during the past eight

or nine years, it had been in the development of the two-stage operation; this was the operation of choice, whether the patient was in good condition or not. The one-stage operation was too severe. The time between the two operations usually was about one week. The length of the after-treatment of these cases was not increased by the two-stage operation for prostatectomy. To get good end results from prostatectomy, it was important to make a correct diagnosis before operation. Locomotor ataxia caused bladder symptoms similar to prostatic hypertrophy. The cases should always be examined carefully to exclude a spinal cord lesion.

Dr. Parker Syms said that he had not resorted to the various methods which had been in vogue; that he could not be designated, as Dr. Chetwood had designated himself, a universalist in the religion of prostatectomy, but that he might be more properly classed as a genito-urinarian, for he still believed in one good thing, viz., perineal prostatectomy. Prostatectomy by the perineal route was his choice, for at least in his hands it had afforded very satisfactory results. The successful performance of this operation depended on a proper understanding of the anatomy. Thereby one should be able to operate with the least possible damage and mutilation, and with the best of end results. If one found the proper line of cleavage and adhered to it, there would be very little bleeding and very little shock, and there would be the preservation of the bladder structures and restoration of its function. When they first entered this field of surgery there were two things they dreaded—tight stricture, due to the necessary traumatism on the one hand, and incontinence of urine due to the mutilation of the bladder sphincters, on the other hand. In Dr. Syms' experience, stricture had not followed as an end result of prostatectomy. At first he used to sound these patients at short intervals; now he only used the sounds two or three times during the course of healing. Incontinence of urine was a condition about which he was no longer apprehensive.

So far as the speaker knew, he had had but two cases on his list; one of these had had incontinence produced by an operation of another surgeon, before he operated upon him, so that he did not feel that his operation could be held accountable for it. The second case was in a very feeble man, in the neck of whose bladder he was obliged to leave a fragment of stone until about two weeks after the operation. Dr. Syms thought this kept the bladder neck open, so it healed with a large caliber. He desired to report another case of a man whom he operated upon about a year ago. He recently saw him, because it was said that this man had incontinence. He injected 8 oz. of fluid into his bladder and had him hold it for a considerable length of time, showing that he had control. This man was senile and feeble, and Dr. Syms thought that he could be made to hold his water satisfactorily by proper training. He had found gymnastic exercises of great benefit. When a man became able to retain a small quantity of urine for a few minutes, he knew that he would soon regain complete control. Dr. Syms had on his list one case of rectoperineal fistula. He believed that this accident occurred after the operation but, of course, that might not be so. One of the most noticeable end-results of prostatectomy was the regeneration of the patient, owing to his relief from autointoxication. This autointoxication, which was due to the backing up of the urine and the consequent inefficiency of the kidneys, was a marked feature of prostatic obstruction. Many a man, after his relief, improved to an extent amounting to rejuvenation. He would be physiologically ten or fifteen years younger than he was before the operation.

Dr. Martin W. Ware said that it seemed illogical to listen to an enumeration of the ill effects following prostatectomy, some of the gentlemen stating that they had not seen a single instance of stricture, or fistula, or of incontinence of a permanent nature; and yet nearly all the speakers had told at length what they had done to prevent the occurrence or likelihood of fistulæ. There was no doubt that the success of this operation depended upon a sound knowledge of the anatomical basis. The mortality following this operation in the genitourinary service of the hospital was about 10 per cent. One should attempt to minimize the evil effects and also the mortality by a careful selection of the cases. After all, either operation accomplished in the vast majority of the cases results that they set out to obtain, placing the patients in a better position physically than before. Dr. Ware contradicted Dr. Wiener's statement in regard to never having seen a fistula follow suprapubic operation.

With regard to potency, Dr. Ware recalled that Allawan invariably found impotence following perineal operation. Some experiments were made by Albarran's assistant on rodents; he removed the prostates from these animals, and found them to be still potent. Walker of England had also removed the prostate from animals, and reported the same result. Dr. Ware closed his remarks by relating a rare sequel, an instance of myositis ossificans occurring in the rectus muscle following the operation of suprapubic prostatectomy, and referred to hernia occurring in the line of the cicatrix.

Philadelphia Neurological Society.

At a stated meeting held January 28 Dr. Wharton Sinkler exhibited "A Case of Acute Anterior Poliomyelitis Involving the Upper Extremities." The patient was a young man who presented weakness and wasting of the muscles of the upper extremities, without degenerative electric reactions, and with exaggerated knee-jerks, in the sequence of an acute illness with elevation of temperature and other symptoms of infection. The lower extremities were in no way affected, and the action of the sphincters was under control. There had been no loss of consciousness, and sensibility had been in no way disturbed. The case was looked upon as one of acute anterior poliomyelitis with unusual symptomatology.

After the presentation of this case Dr. Francis X. Dercum exhibited a "Case of Scleroderma with Sclerodactyly." The patient was a woman presenting widespread tightness and induration of the skin, associated with pain and tenderness in the affected parts. The fingers and toes presented at times marked pallor or whiteness, at other times cyanosis and redness. No change in the size of the thyroid gland was demonstrable.

Dr. Augustus A. Eshner then exhibited "A Case of Mercurial Tremor." The patient was a man 50 years old who had been engaged for the past fifteen years in the manufacture of felt hats. He had complained for a few months of general tremulousness and weakness, and he presented a coarse tremor of the fingers, as well as tremor of the tongue and facial muscles. The knee-jerks were preserved. There was no nystagmus. A solution of mercury in nitric acid was employed in the preparation of the felt, and men engaged in this process suffered at times from the "shakes." Drinking of milk and abstinence from alcohol were practised with more or less success as prophylactic measures.

Dr. Alfred Gordon exhibited a "Case of External Ophthalmoplegia followed by Exophthalmic Goiter." The patient was a woman who presented weakness of the external rectus of the right eye, and of the superior rectus of both eyes, with retraction of the eyelids, a staring, fixed expression, and exposure of the sclerotic above the cornea, enlarged thyroid gland, fine tremor of the fingers, and moderate tachycardia. Referring to another case of exophthalmic goiter associated with paresis of the third, fourth,

and sixth cerebral nerves Dr. Gordon contended that these cases, together with the experimental and pathological evidence, lent support to the view that exophthalmic goiter is due to a lesion of the medulla oblongata, with secondary involvement of the thyroid gland and the development of the remaining symptoms. Dr. Gordon exhibited also "A Case of Anterior Poliomyelitis of Unusual Distribution." The patient was a lad with loss of power in the trapezius and scapular muscles on the left side and of the deltoids on both sides, together with fascicular twitching in some of the affected muscles. Dr. Gordon exhibited further "A Case of Hysteria with Vasotrophic Disorder." The patient was a neurotic young man, who, in addition to other evidences of hysteria, exhibited in the sequence of depressing emotional influences circular erythematous areas of sudden development above the breasts and on the neck, and it was thought that self-mutilation could very definitely be excluded.

Dr. Tom A. Williams of Washington demonstrated "A Method of Estimating Cerebellar Dysergia." This consisted in making a horizontal line and marking on it three points at different distances and then making a second line at right angles to the first and marking on it also three points at different distances. The test was made by having the patient attempt with pencil or pen to draw lines from the points on the vertical line to the distances marked on the horizontal line and parallel to this line. The amount of dysergia would be indicated by the distance beyond the desired point the lines were drawn, and more especially the distance they were drawn backward from the extreme. Dr. Williams demonstrated also "An Apparatus for Ready Clinical Investigation of the Sensibility of Coolness and Warmth." This consisted of a thermometer encased in a block of wood and having its lower portion surrounded by a casing of copper, as the next best conductor to silver. By immersion in water of a known temperature the copper would maintain the given temperature for a time sufficiently long to make the desired examination. Dr. Williams also reported "An Anomaly of Sensibility in the Course of an Acute Serous Meningitis." This was observed in the case of a man who had been thrown from a horse and exhibited in addition to other phenomena of meningitis dissociation of sensibility in one lower extremity.

Dr. Milton K. Myers reported "A Case of Paralysis Agitans with Occasional Slight Tremor; Vitiligo the First Symptom."

Dr. William Burdic presented a communication entitled "A Study of Functional Exercises in Some Nervous Diseases." He discussed the usefulness of coordination exercises in the restoration of industrial usefulness in cases of tabes, spastic states, paralysis agitans, and other conditions. In every instance the exercises should be selected with regard to the occupation or activity of the individual patient. Muscles or members long not used or incorrectly used require reeducation, and while the process is at times tedious and time-consuming the results constitute sufficient reward for the effort.

Dr. Samuel Stern then presented an interesting communication which was entitled "Kernig's Sign: Its Presence and Significance in General Paresis of the Insane and in Arteriocapillary Fibrosis." Inability to extend fully the leg of a patient in the dorsal decubitus with the thigh flexed at a right angle to the trunk is observed in cases of meningitis, and has been thought to be due to involvement of the pia mater. In an extended investigation Dr. Stern found the sign present in a large number of cases of general paresis, and in a considerable number of cases of arteriocapillary fibrosis, and in cases of tabes dorsalis associated with arteriosclerosis. In all of these it was thought that the manifestation was due to associated leptomeningitis.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Massachusetts Board of Registration in Medicine.

March 7, 1910.

ANATOMY AND HISTOLOGY.

1. Describe the arrangement of the dura mater and state functions.
2. Make a diagram of the stomach, moderately distended, and state its anatomical relations.
3. Describe the portal circulation and state how it is connected with the systemic.
4. What is Poupart's ligament? State origin and insertion, and the structures which pass under it.
5. Describe a muscle fiber. Name three parts of the body in which unstriped muscle is found.
6. State origins of vertebral, internal mammary, and basilar arteries.
7. Name the largest cranial nerve. How many roots has it, and what is its superficial origin? Why is it called a compound nerve?
8. Make a diagram of the second nerve. What is its exclusive distribution?
9. Locate and give the gross anatomy of the medulla oblongata.
10. Oral examination.

PHYSIOLOGY AND HYGIENE.

1. State the functions of the fifth nerve.
2. Trace the nervous path in case of reflex action. Is walking a reflex?
3. What is the purpose of the Haversian canals? What is the function of the marrow and the periosteum?
4. Name and locate the valves of the heart and state their functions. What is the velocity of the blood current?
5. When food of various types is digested, where and in what way does it enter the blood stream?
6. Describe the phenomena which occur when muscle is in a state of activity.
7. What objections may be given to heating dwelling rooms by direct radiation from stoves and from steam or hot water pipes? What would you recommend as a substitute?
8. What conditions tend to prolong the life of a bacillus outside of the body?
9. Mention diseases where germs are carried by water; also by air.
10. Oral examination.

PATHOLOGY AND BACTERIOLOGY.

1. Differentiate death by drowning and death by strangulation.
2. Name and describe five abnormal constituents of urine which signify disease. How are they determined?
3. State pathological conditions for relief of which diuretics are generally administered.
4. Describe a tubercle. What is its origin and what tissues are most frequently invaded by it?
5. Give the pathology of the initial, the secondary, and the tertiary stages of syphilis.
6. Why does metastasis in carcinoma occur through the lymphatic system and sarcoma through the venous system?
7. What classification is made of bacteria based on the shape of the individuals?
8. What classification of the cocci, based on the arrangement of the individuals composing the groups, can you mention?
9. What bacterium is associated generally with specific urethritis? How may it be determined?
10. State the pathology of hydrocele.

DIAGNOSIS AND THERAPEUTICS.

1. What is glaucoma? Discuss symptoms and treatment.
2. Define and differentiate hallucinations, delusions, and illusions.
3. Describe paralysis agitans. Give etiology and prognosis.
4. Describe characteristic findings in the urine in a case of acute nephritis.
5. Give the symptoms indicating intestinal perforation in typhoid fever. What treatment may avail?
6. Outline the treatment of a case of diphtheria by the use of antitoxin. What is the principle upon which the antitoxin treatment is based?
7. How should an abscess of the middle ear be treated? What serious complications may arise from such an abscess?

8. What are the indications and contraindications as to the use of digitalis as a cardiac stimulant?

9. Differentiate diabetes mellitus and diabetes insipidus. What treatment does the latter demand?

10. What is the significance of the patellar reflex as indicative of disease?

PEDIATRICS AND TOXICOLOGY.

1. Symptoms and treatment of tuberculosis of the nose; also of the eye and of the ear.

2. Describe tuberculosis of the lymphatic glands and outline treatment.

3. State the nature, symptoms, course, and treatment of Pott's disease.

4. Describe scabies. How would you treat a well developed case?

5. Describe and differentiate pemphigus and varicella.

6. Describe catarrh of the middle ear; etiology, symptoms, course, and treatment.

7. Arriving within five minutes after your patient has swallowed a 2-ounce solution containing 5 to 8 grains of cocaine hydrochlorate, in what condition would you expect to find him, and what would you do for him?

8. Arriving an hour after your patient had taken cocaine as mentioned in question 7, in what condition would you expect to find him, and what would you do for him?

9. State in detail what you would consider the most efficient treatment, when promptly administered, for a patient who has swallowed a dangerous dose of carbolic acid? Should the treatment be delayed for half an hour to an hour after ingestion of the dose, what would be your treatment?

10. In what manner does death ensue in poisoning by hydrocyanic acid, by aconite, by morphine, by atropine, by strychnine?

SURGERY.

1. Give etiology, symptoms, and treatment of empyema. State usual results when not treated.

2. Differentiate chancre and chancroid, and state treatment for each.

3. State the symptoms of fracture of both bones of the forearm in their middle third. How would you treat a case?

4. State the causes of nonunion in bone fractures. What should be the treatment in such cases?

5. Differentiate piles, fistula, and fissure. Treat the last.

6. Discuss ascites—causes, differential diagnosis, and treatment.

7. Give the symptoms of renal calculus. State cause and treatment during an attack, and also treatment in the interval between attacks.

8. State the diagnostic points in prostatic hypertrophy. Give palliative treatment.

9. Define psoas abscess. What is the nature of its fluid? What can you say as to its treatment?

10. Oral examination.

OBSTETRICS AND GYNECOLOGY.

1. Discuss the conditions which may render anesthesia advisable during labor. What anesthetic would you use, and how would you administer it?

2. Define second stage of labor and state the conditions which may cause delay of delivery in this stage, and how such conditions should be managed.

3. Describe toxemia as noted in pregnancy, and state measures of prevention and of alleviation.

4. Define endometritis and state cause, symptoms, and treatment.

5. Should the head of the child fail to enter the pelvic brim, how would you conduct your case of labor?

6. Mention not less than four conditions liable to cause prolapse of the cord, and outline the treatment for any one condition mentioned.

7. Differentiate the uterus of a virgin and that of a multipara, as observed in post-mortem examination.

8. Discuss possible injuries to the birth-canal incident to labor. How and when are they best discovered, and state how they should be treated.

9. How can you differentiate uterine and vaginal leucorrhea?

10. Discuss gonorrhea in women—symptoms and far-reaching results.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

MASSACHUSETTS BOARD OF REGISTRATION IN MEDICINE.

March 7, 1910.

ANATOMY AND HISTOLOGY.

1. For *arrangement of dura*, see Cunningham's "Anatomy" (1909), page 597; or Gray's "Anatomy" (1908), page 972. The *function of the dura* is protection: It forms the internal periosteum of the skull, it forms three partitions for the support of the parts of the brain, it forms sinuses or venous channels for the return of the blood from the brain, and it forms sheaths for the nerves as they leave the skull.

2. See Cunningham's "Anatomy" (1909), page 1051; or Gray's "Anatomy" (1908), page 1277.

3. See Cunningham's "Anatomy" (1909), page 1120; or Gray's "Anatomy" (1908), page 768.

4. Poupart's ligament is formed by the lower border of the aponeurosis of the external oblique muscle; it extends from the anterior superior spine of the ilium to the spine of the pubes. The anatomical structures which lie beneath Poupart's ligament are (from without inward): External cutaneous nerve, Iliacus, anterior crural nerve, Psoas, femoral artery, femoral vein, femoral ring.

5. See Gray's "Anatomy" (1908), page 364. Three places in which unstriped muscle is found: Arteries, stomach, intestines.

6. Vertebral artery is from subclavian artery; internal mammary artery is from subclavian artery; basilar artery is from two vertebral arteries.

7. The largest cranial nerve is the fifth, or trigeminal. It has two roots. Its superficial origin is from the side of the pons Varolii, nearer to the upper than the lower border. It is called a compound nerve because it contains both motor and sensory fibers.

8. See Cunningham's "Anatomy" (1909), page 676; or Gray's "Anatomy" (1908), page 1038. It is distributed exclusively to the retina.

9. See Cunningham's "Anatomy" (1909), page 481; or Gray's "Anatomy" (1908), page 874.

PHYSIOLOGY AND HYGIENE.

1. THE FUNCTIONS OF THE FIFTH CRANIAL NERVE. *First ophthalmic branch* supplies sensation to conjunctiva and skin of upper eyelid, cornea, skin of forehead and nose, lacrymal glands, mucous membrane of nose. *Second, or superior maxillary branch*, supplies sensation to skin and conjunctiva of lower lid, nose, cheek, upper lip, upper teeth and alveolar processes, and palate. *Third, or inferior maxillary branch*, supplies sensation to external auditory meatus, side of head, mucous membrane of mouth, anterior two-thirds of tongue, lower teeth, lower lip, and skin of the lower part of the face. This branch, in addition, supplies motion to the muscles of mastication (Masseter, Temporal, External, Pterygoid, Internal Pterygoid), also mylohyoid, and anterior belly of digastric.

2. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve. Reflexes are classified as: (1) Superficial, (2) deep, and (3) visceral. *Example:* The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendons, afferent or sensory nerve, pulsterior roots, and anterior horn of the spinal cord; the efferent or motor nerve, and the muscle itself. Strictly speaking, *walking* is primarily a voluntary act; but practically it may be considered as a reflex.

3. *The Haversian canals* serve to conduct arteries, veins, lymphatics, and nerves to and from the bone substance. The *marrow* supports the blood-vessels, is concerned in the formation of bone, also nourishes spongy bone, and forms red blood corpuscles. The *periosteum* acts as a protection to the bone; also generates bone, aids in the repair of bone, and takes part in the nourishment of bone.

4. *The valves of the heart* are: In the *right auricle*, the Eustachian and coronary valves; the former is situated between the anterior margin of the inferior vena cava and the auriculoventricular orifice. In the fetus it directs

the blood from the inferior vena cava through the foraman ovale into the left auricle; the coronary valve prevents the regurgitation of the blood into the coronary sinus during the auricular contraction. In the *right ventricle* are the tricuspid and semi-lunar valves; the former prevents the blood in the right ventricle from flowing back into the right auricle during ventricular cystole; the latter guards the orifice of the pulmonary artery. In the *left ventricle* are the mitral and semi-lunar valves; the former acts similarly to the tricuspid; the latter guards the orifice of the aorta. Aortic valves, behind the third intercostal space, close to the left side of the sternum. Pulmonary valves, in front of the aortic, behind the junction of the third rib, on the left side, with the sternum. Tricuspid valves, behind the middle of the sternum, about the level of the fourth costal cartilage. Mitral valves, behind the third intercostal space, about one inch to the left of the sternum. *The velocity of the blood current* is about one foot per second in the arteries; about one inch per minute in the capillaries; and about eight inches a second in the veins. The complete circulation around the body is said to occupy a little less than half a minute.

5. The products of digestion find their way into the blood by two routes: (1) By the blood-vessels of the gastrointestinal tract, which unites to form the portal vein, and (2) by the lymph vessels of the small intestines, which converge to empty into the thoracic duct. The water, inorganic salts, proteids, and sugar go by way of the portal vein to the ascending vena cava; and the fats go by way of the thoracic duct to the junction of the left subclavian and internal jugular veins.

6. *When a muscle is in a state of activity:* (1) It becomes shorter and thicker, but (2) there is no change in volume; (3) there is an increased consumption of oxygen; (4) more carbon dioxide is set free; (5) sarcolactic acid is produced; and hence (6) the muscle becomes acid in reaction; (7) it becomes more extensible, and (8) less elastic; (9) there is an increase in heat production and consequently a rise of temperature; (10) the electrical reaction becomes relatively negative; and (11) a sound is produced.

7. The objection to *stoves* is that the air gets dry and unpleasant, the air is thus often hotter than the walls and floor, and so chills are produced; the presence of carbon dioxide is often noted. *Steam or hot-water pipes* are about as good a method of heating a house as any known.

8. *Conditions that tend to prolong the life of a bacillus outside of the body:* Moisture, rest, moderate warmth, dim light, alkaline medium, and suitable nourishment.

9. Diseases whose germs are carried *by water:* Typhoid, cholera, dysentery, sometimes diphtheria; germs are carried *by air:* Tuberculosis, scarlet fever, measles, smallpox, pneumonia, influenza, diphtheria, and erysipelas.

PATHOLOGY AND BACTERIOLOGY.

1. *In death by drowning:* The surface is pallid, the face appears tranquil, the eyes and mouth being partly open. The skin often has the appearance known as gooseskin, and, if the body has lain upwards of twelve hours in the water, that of the hands and the feet is sodden by imbibition. The most important external sign is the presence on the mouth and nostrils of a fine froth (possibly blood stained), composed of air, mucus, and the medium in which drowning took place; if the body remains three or four days in water, the froth disappears. Exceptionally, fragments of weeds or other small objects may be found tightly grasped in the hands. On opening the thorax the lungs, gray in color, with reddish staining, are seen to be very voluminous, a condition known as ballooning, partly due to infiltration of the lung tissue with some of the medium in which drowning took place, and partly to true edema. The lung substance is inelastic and pits on pressure. On section, fluid and froth resembling that found on the lips exude from the divided air passages. Minute subpleural hemorrhages are not infrequently present, and the pleural cavities may contain fluid. The stomach often contains water or other liquid which was involuntarily swallowed during attempts at respiration. Occasionally some of this fluid is forced by vital action into the intestines. With one exception, the remaining appearances are those met with after death from asphyxia. The exception is constituted by the blood, which is not only dark colored and fluid, as is usual after death from asphyxia, but is also diluted by the imbibition of water from the stomach and lungs.

In death by strangulation: The blood is of a dark color, owing to complete reduction of the hemoglobin. The proportion of carbonic acid is increased, and owing to its excess the blood coagulates slowly or imperfectly; hence it remains fluid or forms few and soft coagula. The large veins, the pulmonary artery, and the cavities of the right side of the heart may be distended with dark fluid blood, but this is by no means necessarily the case. The left side is usually empty or nearly so. The lungs may be congested, but are often pallid and anemic, though the dependent parts usually exhibit appearances of hypostatic engorgement. The abdominal viscera, especially the kidneys, are often congested. The appearance of the brain varies; it may be anemic or more or less congested. Special signs characterize special modes of causation of asphyxia. Very commonly punctate ecchymoses are visible on the conjunctiva, face, neck, and chest. They are considered by Tardieu to be more frequent in strangulation than in asphyxia from other causes, or than in cases of overstraining, which likewise may lead to them. In the subcutaneous cellular tissue, and in the fascia of the muscles above and below the hyoid bone extravasations are frequently found, as well as on the external surface of the thyroid cartilage and trachea. The lungs vary as regards their vascularity; but on the surface it is common to find pseudomembranous patches, which are due to the rupture of some of the superficial air cells and collection of air bubbles under the pleura. In the substance of the lungs congested patches, or apoplectic extravasations, are often found, varying in size, but larger than those usually found in suffocation.—(From Quain's *Dictionary of Medicine.*)

2. Five abnormal constituents: Albumin, sugar, blood, bile pigment, and excess of indican.

Test for *albumin:* The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture and again filtered. The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

Test for *sugar:* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

Test for *blood:* To the urine add a solution of potassium hydroxide to distinct alkaline reaction; heat nearly to boiling (do not boil). A red precipitate is produced.

Test for *bile pigment:* Put 3 c.c. HNO_3 in a test tube, add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquid, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

Test for *indican:* The urine is mixed with one-fifth its volume of 20 per cent. solution of lead acetate and filtered. The filtrate is mixed with an equal volume of fuming hydrochloric acid containing 3:1000 of ferric chloride, a few drops of chloroform are added, and the mixture strongly shaken one to two minutes. With normal urine the chloroform remains colorless, or almost so; but if an excess of indoxyl compounds be present the chloroform is colored blue, and the depth of the color is a rough indication of the degree of the excess.

3. *Indications for the use of diuretics:* (1) To remove excessive fluid from the tissues, as in dropsy; (2) to dilute the urine; (3) to promote the elimination of waste products, or poisonous material from the blood; and (4) to maintain the action of the kidneys.

4. A *tubercle* is a small nodule, found in the lungs, etc., in cases of tuberculosis, but also found in other diseased conditions. It consists of three layers, the outer one consisting of lymphoid cells, the middle one of epithelioid cells, and the inner one of giant cells. These layers are squeezed or compressed into a firm mass, which may caseate or undergo other pathological processes. There is no blood supplied to a tubercle. Its *origin* is due to the stimulating or irritating effects of the tubercle bacillus upon the fixed connective tissue elements, causing a round-cell proliferation. The *tissues most frequently invaded by it* are: Lungs, lymphatic glands, bones, joints, intestinal tract, peritoneum, skin, testicle, epididymis, brain, liver, kidneys, spleen, Fallopian tubes, ovaries, uterus.

5. See French's "Practice" (1907), page 420; or Osler's "Practice (1909), page 267; or Rose and Carless' "Surgery" (1908), pages 144, 148, and 151; or Da Costa's "Surgery" (1908), pages 276, 279, and 284.

6. In carcinoma lymphatics are found in the stroma, which abounds; in sarcoma there are no lymphatics, but the blood vessels are in direct contact with the tumor cells.

7. Bacteria are classified as follows: (1) the coccus, which is spherical; (2) the bacillus, which is rod-shaped; and (3) the spirillum, which is spiral.

8. Cocci are classified as follows: Diplococci, occurring in pairs; sarcinæ, occurring in bales; streptococci, occurring in chains; and staphylococci, occuring in bundles.

9. The bacterium generally associated with specific urethritis is the gonococcus of Neisser. The gonococcus is a diplococcus, and is recognized by staining with the ordinary aniline dyes, being found inside the pus cells; it is Gram negative, and can be cultivated on human blood serum, but will not grow on the ordinary culture media.

10. See Rose and Carless' "Surgery" (1908), page 1265.

DIAGNOSIS AND THERAPEUTICS.

1. *Glaucoma* is a diseased condition of the eye, produced by increased intraocular pressure, and resulting in excavation and atrophy of the optic disc, and blindness. It is due to increase of the contents of the eye, hypersecretion, retention, old age, gout, rheumatism, nephritis. *Symptoms:* Visual disturbances, increased ocular tension, hazy and anesthetic cornea, sluggish and dilated pupil, shallow anterior chamber, ciliary neuralgia, cupping of optic disc, blindness. *Treatment:* Myotics, such as eserine or pilocarpine; massage of the eyeball; mydriatics are contraindicated; operative treatment may include paracentesis, iridectomy, or sclerotomy.

2. A *delusion* is a belief in something which has no real existence, but is purely imaginary, and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression, received through one of the senses. An *hallucination* is the same as an illusion, but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion*. If the whistling of the wind is mistaken for a voice telling a person to do a certain thing, that would be an *illusion*. If a person fancied he heard a voice when there was nothing at all to be heard, that would be an *hallucination*.

3. See French's "Practice" (1907), page 1114; or, Osler's "Practice" (1909), page 1042.

4. See French's "Practice" (1907), page 893; or, Osler's "Practice" (1909), page 688.

5. *Intestinal perforation in typhoid fever:* Sometimes there is severe, sudden pain localized in the abdomen, and sometimes there is little or no pain. Marked tympanites, great weakness, collapse, anxious look, small, rapid pulse, and difficult breathing are present. The legs are apt to be drawn up, and nausea and vomiting may ensue. Hepatic and splenic dullness appear, and leucocytosis may be present. The treatment is surgical; laparotomy, with suture of the intestine, should be done as soon as possible. In the meantime opium (or preferably morphine) should be administered.

6. See French's "Practice" (1907), page 196; or, Osler's "Practice" (1909), page 209.

7. *Treatment of abscess of the middle ear:* Leeches, free incision followed by boric acid irrigation or by insufflation of dry boric acid powder. *Complications that may arise:* Eczema, boils, arthritis of temporo-maxillary joint, ankylosis or necrosis of the ossicles, facial paralysis, mastoiditis, subcranial abscess, meningitis, thrombosis of the lateral sinus, cerebral abscess.

8. Digitalis is *indicated* in diseases of the heart: (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in non-valvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is *contraindicated* in diseases of the heart: (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong and arterial tension is high.

9. See French's "Practice" (1907), pages 935, 947, and 949; or, Osler's "Practice" (1909), pages 408, 424, and 425.

10. The *patella reflex* is nearly palways *present* in health, and denotes a healthy condition of the entire reflex arc (tendon, afferent or sensory nerve, posterior roots and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself). It is *absent* when there is a lesion which affects any part of this reflex are, such as is the case in locomotor ataxia, poliomyelitis, Landry's paralysis, neuritis, in apoplexy just after the shock, and in epilepsy following the convulsion, etc. It is *exaggerated* in: Hemiplegia, lateral sclerosis, general paresis, transverse myelitis, injuries to the spinal cord, hysteria, neurasthenia, tetanus, and strychnine poisoning.

PEDIATRICS AND TOXICOLOGY.

1. TUBERCULOSIS OF THE NOSE: "Tuberculosis of the nose is characterized by the formation of neoplasms or ulceration of the mucous membrane, and often accompanies a general pulmonic tuberculosis. *Symptoms:* In the ulcerated form there is an accumulation of crusts which are blown from the nose. There may be more or less stoppage of the nose, perforation of the septum, and nasal catarrh. In the neoplastic form, there is nasal obstruction and symptoms of hypertrophic catarrh. *Treatment:* In the necrotic form of the disease the nose should be sprayed twice daily with a mild alkaline spray, followed by an oil spray containing acetozone. Small papilla-like growths may be destroyed with the galvano-cautery or removed with snare and scissors. It is advisable to refrain as far as possible from surgical procedure in the nasal cavity in a general tuberculosis. The general treatment is directed to combating the tubercular infection by tonics, sunshine, and outdoor life."

TUBERCULOSIS OF THE EAR. "*Symptoms:* The ear symptoms frequently appear after the lung complications are established. There may be tinnitus, followed by deafness and painless rupture of the drum, and a thin mucous or mucopurulent discharge. On the other hand, the symptoms may vary in no wise from simple acute otitis media. *Treatment:* The surgical treatment is the same as for acute or chronic otitis media. Outdoor exercise and nutritive diet are especially essential."—(J. J. Kyle's *Manual of Diseases of the Ear, Nose, and Throat.*)

TUBERCULOSIS OF THE EYE. "*Tuberculosis of the conjunctiva:* A rare condition, most frequently associated with lupus of the skin of the face. It is characterized by large, soft granulations in the fornices, studded with miliary tubercles. Usually there is some infiltration of the sclerocorneal margin and of the cornea, so that vision is reduced. *Treatment* is best effected by thorough removal of the granulations by scraping and subsequent insufflation with iodoform." *Tubercular iritis: Symptoms:* "This is most frequently seen in children and young adults. It is of a quiet, painless, and chronic type. Miliary tubercles are to be seen in the iris—small grayish nodules, with a few pink vessels about them. They usually appear at the root of the iris, close into the angle of the anterior chamber, but may affect the border of the iris. Spots of lymph of large size, like spots of mutton fat, may be seen on the back of the cornea, indicating cyclitis. In other cases these symptoms may be complicated by a sclerokeratitis. These are of a more severe order, and shrinkage of the eyeball may result. The diagnosis of tubercle is not easy. We may exclude syphilis by history, by the balance of the symptoms, and by the response to treatment. The reaction to injection of Koch's tuberculin or the newer ophthalmoreaction of Calmette may be utilized, or the aqueous may be tapped and inoculated into rabbits."—(*Aids to Ophthalmology.*)

2. *Tuberculosis of the lymphatic glands* occurs most commonly in people under twenty years of age; hereditary disposition and lowered vitality are predisposing factors. The tubercle bacilli reach the glands either by the blood or lymph or through mucous membrane. The glands are enlarged and firm; later they run together and caseate and frequently suppurate. Later still periadenitis fixes the mass to the deeper structures and to the skin. Still later the abscess bursts on the surface, leaving one or several openings and discharging pus for a long time. *Treatment:* Improve the general health by fresh air, sunshine, arsenic, cod liver oil, iron, and good nourishing food. The gland or whole glandular chain may be dissected out in cases where periadenitis is present. Where there is an unopened abscess, either excise and drain or dissect out.

3. See Rose and Carless' "Surgery" (1908), page 718; or, Da Costa's "Surgery" (1908), page 747.

4. *Scabies* is a contagious, animal, parasitic disease, due to the *Sarcoptes scabiei*, characterized by burrows and a multiform eruption, and attended by severe itching. The eruption usually occupies certain areas where the skin is thin; these are the interdigital spaces, the flexor surface of the wrist and arm, the anterior and posterior axillary folds, the mammæ and nipples (in women), the umbilicus, the buttocks, the penis, the inner side of the thighs and legs, and the toes. The face is exempt except occasionally in infants. The itching is intense and worse at night. The affection is curable, but dermatitis may result from overtreatment. *Treatment* consists in a thorough scrubbing with soap and warm water, followed by friction to dry the skin, and the application of sulphur ointment, the latter to be repeated morning and night for three days. The whole process may need to be repeated one or more times.

5. *Pemphigus* is an acute or chronic inflammatory dis-

ease of the skin, characterized by the formation of successive crops of variously sized, rounded or oval bullæ affecting seriously the general health and sometimes terminating fatally. The blebs of pemphigus are tense, abruptly elevated, noninflammatory, and come out in crops. For *Varicella*, see French's "Practice" (1907), page 313; or, Osler's "Practice" (1909), page 128.

6. "*Acute catarrhal otitis media* is frequently caused by acute coryza and the infectious fevers. There is a painless obstructed sensation in one or both ears, impairment of hearing, and tinnitus. The inflammation causes closure of the Eustachian tube. Inflation and aspiration of the middle ear and syringing and douching the nares and nasopharynx must be avoided. A moderate spray of Dobell's solution may be used. If pain is present, dry heat, in the form of hot-water bottle, hot stone wrapped in flannel, etc., may be applied. A few drops (100), warmed, of a carbolic acid solution (1:40), or one of formalin (1:2000), may be instilled into the ear.

"*Acute purulent otitis media:* Acute catarrhal otitis media, instead of undergoing resolution, may pass into acute purulent otitis media (especially in exanthemas) from the passage of pathogenic germs from the nasopharynx into the middle ear. The pain will become more intense, the hearing dull; tinnitus will become louder and more distressing, and fever usually sets in. Dry heat allays the pain. Warmed water or warmed carbolic acid solution (1:40) may be used. Inflations, aspirations, etc., should be avoided. If the nares are filled with tough secretions, a spray of Dobell's solution may be used. If the pain continues over six hours in a child or over twelve hours in an adult without spontaneous perforation of the tympanic membrane, paracentesis of that structure should be performed. The concha and meatus should be smeared with petrolatum to avoid chapping, and the secretions should be gently mopped off as they appear. Under this treatment the ear usually returns to normal in two to three weeks." (Gould and Pyle's *Pocket Cyclopedia of Medicine and Surgery.*)

7. The patient will probably be found with pulse increased in frequency and fulness; the respirations more rapid, much general nervous excitement, and general hyperesthesia. Empty the stomach, give stimulants; adrenalin is said to be antagonistic; nitroglycerine, amyl nitrite, ammonium carbonate and strychnine, and caffeine have all been recommended. Artificial respiration may be necessary; mustard plaster over the heart and stomach may give relief.

8. The patient is now probably in the stage of depression, with shallow breathing, rapid heart action, and pale or cyanotic face. Chloroform or ether may be given subcutaneously, and the measures mentioned in question 7 may be adopted.

9. Alcohol (four to eight ounces of whiskey) followed by water is probably the best treatment when seen immediately. Later on some soluble sulphate, such as sodium sulphate or magnesium sulphate, is the proper treatment.

10. In *poisoning* by *hydrocyanic* acid, death is probably due to asphyxia; by *aconite*, to asphyxia; by *morphine*, usually to paralysis of respiration, occasionally to paralysis of the heart; by *atropine*, to paralysis of respiration; by *strychnine*, to fixation of respiratory muscles.

SURGERY.

1. See Rose and Carless' "Surgery" (1908), page 926; or, Da Costa's "Surgery" (1908), page 773.

2.

CHANCRE	CHANCROID
First lesion of a constitutional disease, viz., syphilis.	A local disease.
Due to syphilitic infection.	Due to contact with secretion from chancroid.
Generally a venereal infection.	Always a venereal infection.
May occur anywhere on the body.	Nearly always on genitals.
Period of incubation never so short as ten days.	Period of incubation always less than ten days (generally about three).
Generally single.	Generally multiple.
Not autoinoculable.	Autoinoculable.
Secretion slight.	Secretion profuse and purulent.
Slightly or not at all painful.	Generally painful.
As a rule only occurs once in any patient.	May reoccur in same patient.
Buboes are painless and seldom suppurate.	Buboes are painful and usually suppurate.

For treatment, see Rose and Carless' "Surgery" (1908), pages 157 and 141; or, Da Costa's "Surgery" (1908), pages 288 and 1180.

3. Rose and Carless' "Surgery" (1908), page 526; or, Da Costa's "Surgery" (1908), page 505.

4. *Nonunion of fracture is caused by:* Ill health, want of approximation of the end of the bone, want of blood supply in the bone, defective innervation of the bone, disease of the bone, lack of rest, and immobility. *Treatment:* "When delayed union exists, seek for a cause and remove it, treating constitutionally if required and thoroughly immobilize the parts by plaster. Orthopedic splints may be of value. Use of the limb while splinted, percussing over the fracture, and rubbing the fragments together, thus in each case producing irritation, have all been recommended. Blistering the skin with iodine or firing it has been employed. If the case be very long delayed, forcibly separate the fragments and put in plaster as a fresh break. If these means fail, irritate by subcutaneous drilling or scraping, or, better, by laying open the parts and then drilling and scraping at many places."

5. Rose and Carless' "Surgery" (1908), pages 1134, 1137, and 1148; or, Da Costa's "Surgery" (1908), pages 1009 and 1012.

6. Ascites is *caused* by: Mechanical obstruction of the portal circulation; cardiac or pulmonary diseases obstructing the general venous circulation; diseases of the peritoneum; diseases of the kidneys; anemia, debility, exposure to cold or wet; cancer, syphilis. *Symptoms:* Generally of gradual onset; abdominal distention, sense of weight and fulness; dyspnea; gastrointestinal disturbances; lineæ albicantes, presence of fluid may be detected by palpation, percussion, or aspiration. If due to heart or lung disease ascites will occur elsewhere, and the legs are generally affected first; in hepatic disorders the abdominal distention is marked, and appears early; in renal disease the abdominal fluid is generally small in amount. *Treatment:* Tapping, drainage, incision, and administration of cathartics have all been recommended. Ovarian tumor, pregnancy, distended bladder, pancreatic cyst, and echinococcus cyst may be mistaken for it. *Ascites is characterized by:* Enlargement of the abdomen, most marked in the flanks when the patient is lying on his back, and in the hypogastrium, when he is standing up; there are dilated superficial veins on the abdomen, and the skin is tense; the umbilicus is prominent; there are fluctuation and vibration on palpation; dulness is found on percussion over the fluid, while the center of the abdomen is resonant.

7. Rose and Carless' "Surgery" (1908), page 1173; or, Da Costa's "Surgery" (1908), page 1110.

8. *Prostatic hypertrophy is characterized by:* Slowness in starting urination; difficult micturition; frequency of micturition, particularly at night; the presence of residual urine; dull, aching pain in the perineum and above the pubes; enlargement of the lateral lobes of the prostate; there may be cystitis and retention of urine. The *cause*: It is a senile change, and may be due to increase of the glandular substance or of the interstitial fibrous or muscular tissue. *Palliative treatment* consists in: Mild and unirritating diet, avoidance of alcohol, taking plenty of milk or water, or other diluent. Alkalies and sedatives should be taken, also urotropin or other antiseptic so as to prevent cystitis. Regular catheterization, at least once a day, preferably in the evening, and with due aseptic precautions.

9. Rose and Carless' "Surgery" (1908), pages 723 and 730; or, Da Costa's "Surgery" (1908), pages 151 and 156.

OBSTETRICS AND GYNECOLOGY.

1. See Williams' "Obstetrics" (1909), page 321; or, Hirst's "Obstetrics" (1909), page 320.

2. The second stage of labor begins when the os is fully dilated, and terminates with the expulsion of the child. Conditions which may cause delay are rigidity, edema, atresia, or displacement of the os or cervix; fibrous bands or atresia of vagina; persistent hymen; unyielding perineum; tumors; distended bladder or rectum; hernia; edema of labia; pelvic deformities; malpositions or malpresentations of the fetus; prolapse of limbs; short cord; large fetus; dead fetus; twins or monstrosities; uterine inertia; rupture of uterus.

3. Williams' "Obstetrics" (1909), page 507; or, Hirst's "Obstetrics" (1909), page 263.

Preventive treatment: (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3)

the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ. *Curative treatment* includes: (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

4. *Endometritis* is inflammation of the mucous membrane lining the uterus. The acute form is due to the introduction of septic bacteria, and is manifested by pain, constipation, irritability of bladder, rapid pulse, rise of temperature, and a profuse discharge. *Treatment* following miscarriage or labor consists in curettage, intrauterine hot sterile douche, free purgation, hot stupes over the lower abdomen, milk diet and stimulants. Chronic endometritis may accompany numerous pathological uterine conditions, but is generally due to gonorrhea. The symptoms are backache, headache, leucorrhea, profuse menstruation, and impairment of the general health. *Treatment* consists in removing the cause when possible, and when due to gonorrhea curettage and irrigation of the uterus, with the application of an antiseptic.

6. See Williams' "Obstetrics" (1909), page 842; or, Hirst's "Obstetrics" (1909), page 625.

7.

VIRGIN UTERUS	UTERUS OF MULTIPARA
The cavity is of normal length and triangular.	The cavity is increased in length, and oval.
The cervix is small, hard, and cartilaginous, and of the same length as the body.	The cervix is large and soft; it is about one-half the length of the body.
The external os is a transverse slit or pinhole orifice with smooth edges.	The external os is irregular and its edges are fissured.
The sides of the cavity of the body are convex inward.	The sides of the cavity of the body are convex outward.
The uterus is normally anteflexed.	The uterus is straighter, or even retrodisplaced.
There is more or less flattening of the anterior and posterior uterine surfaces.	The contour of the uterus is more rounded, while its diameters are increased.
The fundus is nearly flat.	The fundus is convex.
The internal os is closed.	The internal os is patulous.

(From Dorland's *Obstetrics.*)

8. "Tears of the perineum destroy the integrity of the pelvic floor and result eventually in rectocele, cystocele, hemorrhoids, and displacements of the pelvic organs. If the tear involves the sphincter ani, incontinence also results. Lacerations of the cervix retard or check involution of the uterus and predispose to endometritis, menorrhagia, displacements, eversion of the cervical mucous membrane, cystic degeneration, and malignant disease. Deep lacerations of the vaginal vault may open into the base of the broad ligaments, and in the majority of instances genitourinary fistulas are caused by traumatisms of labor. All lacerations are immediately dangerous on account of the increased liability to sepsis, while the remote results are generally due to interference with involution or the pelvic circulation and to the destruction of the normal supports of the pelvis."—(Ashton.)

All tears should be repaired as soon as possible (unless there are contraindications). A primary operation is best because the edges are fresh and can be approximated; little (if any more) anesthetic is wanted; the woman has to lie in bed, and therefore only one absence from household work is requisite; infection is less likely. In any case, operation may prevent rectocele, cystocele, prolapse of uterus, and general weakness, malaise, and disability. For technique, see any text-book on obstetrics or gynecology.

9. Leucorrhea from the vagina is whitish in color, of a creamy consistency. When from the body of the uterus it is a thin, clear, watery, colorless fluid. From the cervix it is a clear, transparent, tenacious, glairy fluid, like white of egg. By means of a speculum the discharge can be seen coming from the uterus in the two latter conditions.

10. *Symptoms:* Pain and burning in the vulva and on micturition; dyspareunia; yellowish or greenish discharge containing the gonococcus; the vagina is hot, red, swollen, and tender. *Possible results:* Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands.

THE ALCOHOL-INJECTION TREATMENT OF TRIFACIAL NEURALGIA.

WITH REPORT OF CASES.

By WILLIAM M. LESZYNSKY, M.D.,

NEW YORK.

NEUROLOGIST TO THE LEBANON AND HARLEM HOSPITALS, ETC.

Of all the peripheral nerves the trifacial, or its branches, is most frequently the seat of neuralgia. We are thus reminded that it is the largest cranial nerve, that it is a nerve of special sense, of common sensation and motion, and that it is the great sensory nerve of the head and the motor nerve of the muscles of mastication.

Many patients during the early stages of trifacial neuralgia will respond promptly to suitable medical (nonsurgical) treatment, the affection terminating in complete and permanent recovery. Desultory and unsystematized management, or impatience of the sufferer, may lead him from physician to physician, until the disease has become chronic and persistent, or ultimately develops into true tic douloureux with its attendant hyperesthesia and agonizing paroxysms. The elimination of affections of the teeth such as dental caries, exostoses or impaction is essential. The same may be said of maxillary or frontal sinusitis and intracranial disease involving the roots of the fifth nerve.

Trifacial neuralgia is frequently symptomatic of intestinal toxemia, and may be relieved by castor oil three times daily, and careful regulation of the diet. Again, rest, galvanism and other forms of electricity are useful. The administration of aconitin, or the subcutaneous injection of strychnin in increasing dosage, have all been followed by more or less success. It is not my object in this paper to enter into therapeutic details. For further elaboration of these outlines of general and special treatment let me refer you to modern text books and to an article by the writer published in the MEDICAL RECORD, March 27, 1897. It is well known that these unfortunate patients are commonly and often unwarrantably subjected to the extraction of numerous healthy teeth, in order to remove a possible dental origin, and are at times, at an early stage of the disease, subjected to nerve resection.

A conservative and safe plan to adopt is the following:—

After rectifying all discoverable sources of irritation, either direct or of reflex origin, should the pain continue unabated, despite the systematic treatment instituted, we may then resort to the injection of alcohol before considering surgical intervention. For those unable or unwilling to submit to any prolonged course of treatment, the alcohol method may be adopted in selected cases.

Within the last few years the treatment of intractable cases of trifacial neuralgia and tic douloureux has been completely revolutionized through the introduction of the injection of alcohol into or in the neighborhood of the foramina of exit of the various nerve branches. Its history, technique and scope are not so well known and familiar to the medical profession as they should be. Before attempting this operation, a preliminary anatomical study on the cadaver and skull is absolutely essential.

Any physician who wishes to undergo this training, can acquire the necessary proficiency for its performance. There is very little likelihood, however, that it will be undertaken indiscriminately by the average practitioner, for suitable cases are not of sufficient frequency to justify the prerequisite preparation. Hence, it is not so likely to fall into disrepute.

The history of the development of this form of treatment is interesting. Schlösser, an ophthalmologist of Munich, was the pioneer in this field, and to him belongs the credit and honor of its discovery. In 1903, in a preliminary report of his investigations, he announced that trifacial neuralgia was easily relieved by the injection of alcohol, and reported several cases of tic douloureux successfully treated in this manner (Bericht über die xxxi Versamml. der ophthalmolog. Gesellsch. Heidelberg 1903, S. 84).

In 1907, at the Congress für Innere Medizin zu Wiesbaden (*Wiener med. Woch.*, June 15, 1907), he reported, that after numerous experimental studies upon animals he discovered that alcohol in the strength of 70 to 80 per cent when brought in contact with a nerve, produced a degeneration of all of its parts excepting the neurilemma. He claimed that the deadening of a nerve with alcohol is equal to a surgical resection. By regulating the dosage, the degree of nerve injury could be controlled. During the preceding five years, he had treated 123 cases of trifacial neuralgia with uniform success. The duration of relief from pain averaged over ten months.

Such marvelous results were previously unknown, and it was not long before the method became deservedly and enthusiastically recognized and warmly advocated. Unfortunately, Schlösser has never published in detail either his technique or his results. His method, however, was subsequently briefly outlined by Ostwalt, one of his students (*Lancet*, June 9, 1906, p. 1605).

Schlösser's method was first introduced to the medical profession in this country by Dr. Otto Kiliani of New York in a paper read before the N. Y. Academy of Medicine (MEDICAL RECORD, December 29, 1906). In his concluding remarks he stated that "it promises to make all operative procedures for these unfortunate sufferers unnecessary." In a subsequent communication (MEDICAL

Record, January 18, 1908) he has statistically reported fifty-five cases treated by this method. In these articles he has referred to the technique only in the most cursory manner. It may here be stated, however, that Schlösser's technique consists in the injection of about two cubic centimeters of sterile alcohol, of strengths varying from 70 to 90 per cent, into the peripheral foramina of exit of the various branches of the trifacial nerve according to the branch involved; *i.e.* at the supraorbital notch, the infraorbital foramen, or the inferior dental foramen. Should these peripheral injections prove ineffectual, the alcohol is injected by the intrabuccal route into the foramen rotundum or the foramen ovale in order to reach the second or third branch.

In 1906 Lévy and Baudouin of Paris (*Presse Médicale,* April 17, 1906) published *their* method of giving alcohol injections in the treatment of trifacial neuralgia. This consists in the employment of a needle 10 ctm. long and 1.5 mm. in diameter. It is introduced through the skin at the lower border of the zygoma to a depth of 4 ctm. to reach the inferior maxillary division of the nerve at its emergence from the foramen ovale, or to a depth of 5 ctm. to reach the second branch as it leaves the foramen rotundum to enter the pterygomaxillary fossa. When the point of the needle has reached the desired location, the alcohol is slowly injected, the needle withdrawn, and the small puncture in the skin covered with collodion.

One year later, Dr. H. T. Patrick of Chicago first directed the attention of the profession to this simpler and equally effective method, in a paper read before the Section on Mental and Nervous Diseases of the American Medical Association (*Journal American Medical Association,* Nov. 9, 1907). In the same number of this Journal, Dr. D'Orsay Hecht, another neurologist of that city, also published a valuable article on this subject. These admirable papers represent an almost exhaustive symposium on the technique and practical utility of the alcohol injection treatment of trifacial neuralgia. In a recent paper (*Journal American Medical Association,* Dec. 11, 1909) Dr. Patrick gives an additional report with brief histories of 75 cases thus treated; 36 patients were between 60 and 70 years old, 13 between 70 and 80, and one over 80. All were perfectly typical cases of tic douloureux. Most of them had passed the fortieth year.

The subzygomatic method of Lévy and Boudouin is more popular in this country on account of its simplicity, and the results are equally satisfactory.

During the last two years I have employed this method, at times, in conjunction with the peripheral injections of Schlösser in the following cases:

Case I.—March 10, 1908. Man, 63. Tic douloureux of a very severe type affecting the third branch on the left side. Duration two years. Twenty-five to fifty attacks daily. They are described as sudden, sharp, electric-like shocks at point of chin, darting upward to the interior of the eye, with twitching of facial muscles, and lasting about thirty seconds. There is no loss of consciousness, but he at once becomes oblivious to his surroundings. At times, he is suddenly aroused out of his sleep. The paroxysms are induced by talking, blowing the nose, sneezing or eating. He has not partaken of solid food for several months, and has lost nearly thirty pounds in weight. He is unable to attend to his business, or go about the streets unattended, for, as soon as an attack occurs, he suddenly grasps his face forcibly, and bends his head and body toward the ground, remaining in this position until the pain subsides. There are no tender points. All of the molar teeth in the left upper and lower jaws have been extracted without relief. March 16. Injection at foramen ovale, the point of the needle touching the nerve at once, as manifested by the patient, who complained, while the alcohol was being injected, of severe burning at the side of the tongue and numbness in the lower part of the face which soon became analgetic. During the next 48 hours he had two very slight pains. March 18. Was feeling quite well and voraciously eating solid food. No pain for one week, and he had gained nearly ten pounds. March 26. Slight attack. Injection 3 c. c. 90 per cent. May 17. Recurrence. This was ascribed to exposure to cold, in getting drenched in a storm and remaining in wet clothing for several hours. Injection repeated. This was followed by complete freedom from pain for several months, when some pain returned in the middle branch. Dec., 1908. In the course of two weeks five injections were given for the middle branch with permanent relief for five months. In May, 1909, very slight pain in middle and inferior branches. One injection given into infraorbital foramen, and three for deep branches. When last seen, May 29, 1909, he was free from pain.

Case II.—April 23, 1908. Man, 48. Second and third branches involved on left side. Duration two years. Usual hyperesthesia of face. Two injections for middle branch. No pain for five months. Oct., 1908. Injection for inferior branch. Complete relief for ten months. Then slight pain in middle branch. Aug. 1909. Injection into infraorbital foramen. No pain since.

Case III.—May 20, 1908. Man, 70. Second and third branches involved. Duration three years. Attack every twenty or thirty minutes, accompanied by spasm. Usual hyperesthesia. Pain more pronounced in third branch, radiating into tongue and pharynx. All teeth had been extracted. Injection near foramen ovale followed by analgesia. Attacks diminished in frequency, and subsided the next morning. Slept all night for the first time in two years. Complains of slight pain in second branch. Injection into infraorbital foramen. Nov., 1908. A few mild pains in third branch. Injection followed by relief for eleven months. He was so comfortable that he refused further treatment.

Case IV.—Sept. 15, 1908. Woman, 64 years old. Third branch affected on right side. Duration six years. Attack every fifteen or twenty minutes, the pain involving the tongue, and, at times, radiating into the ear. Maxillary antrum had been explored and all lower teeth extracted on affected side. She was taking two to three grains of morphine daily. The face was extremely sensitive to the slightest touch. Attack induced by blowing the nose, sneezing, or attempting to masticate or swallow food. Injection was soon followed by analgesia, so that 15 minutes later, the face could be rubbed and stroked without producing an attack. The pain disappeared, and she refused to have another injection unless the pain returned. There was a slight recurrence at the end of nine months. June, 1909. Two injections were given during one week, and she has since been free from pain.

Case V.—Nov. 12, 1908. Woman, aged 56. Second and third branches affected on left side. Duration about six years. All teeth had been extracted and the lower alveolar process "scraped" without relief. Attacks alternate between the two branches,

the pain in the lower branch being more severe, involving the tongue, floor of the mouth, and the pharynx. Paroxysm every five or ten minutes accompanied by spasm of facial muscles. The face is exquisitely sensitive, touching it with a soft camel's hair brush or blowing upon it inducing an attack. Injection for lower branch produced slight relief for a few days. Then, infraorbital foramen was injected, and a week later the third branch was again injected. This was followed by analgesia and complete relief for nearly eight months.

Case VI.—Jan. 28, 1909. Woman, aged 62. Left third branch involved. Duration fifteen years. About six years ago, resection of inferior dental nerve was followed by relief for ten months. The pain then returned and has continued. She has been subjected to many forms of treatment without relief, and has become hypochondriacal and self-absorbed, continually talking about her past and present pains. The attacks are characteristic of tic douloureux. Injection was given for the third branch, and the next day the infraorbital foramen was injected, resulting in cessation of all spasm. Another deep injection was given two days later. Feb. 17. Since last injection all spasm has completely disappeared. The pain is very much diminished and the attacks are less frequent. After much persuasion, she hesitatingly admits that she is very much improved. She sleeps better and has been out driving several times. The pain is confined to the third branch, and there is slight stiffness of the muscles in the lower jaw. Injection given. This was followed by sensation of burning and numbness in the lower lip and chin, and on the side and tip of the tongue. Only slight analgesia was demonstrable (probably on account of the previous resection of the inferior dental nerve). March 31. Very much improved. Only occasional attacks of very slight pain. No spasm since first injection. She is apparently unwilling to admit that she has been benefited by the treatment, although her nurse and various members of the family notice the improvement in her general behavior. She is continually apprehensive as to the return of the attacks, and repeatedly and persistently describes in detail the pain and torture she has endured for so many years. I did not see her again until August 14, 1909, when I learned, that during my absence from the city in July the paroxysms returned, and she received two deep injections without relief, and a few weeks later, two injections into the inferior dental foramen. The latter was followed by persistent spasmodic fixation of the jaw so that she was unable to open the mouth more than one-fourth of an inch. The pain was very much worse, and the attacks were accompanied by tonic spasm of the facial muscles. She had been confined to bed for several weeks, receiving frequent doses of morphine subcutaneously. I found her screaming and crying aloud every few moments and thoroughly demoralized. Injection at the foramen ovale was followed by incomplete analgesia in the peripheral distribution of the third branch. Immediate relief resulted. She soon fell asleep. The morphine was discontinued at once. In a few days she was up and about in every way improved. When last seen, March 11, 1910, she reported that she has been entirely free from pain since the last injection (a period of eight months).

Case VII.—Feb. 13, 1909. Man, aged 54. Right second branch affected. Duration five months. All teeth have been extracted from the upper jaw without relief. March 9, injection into infraorbital foramen, followed by analgesia of face. For several months after the injection, he complained of numbness of the nasal mucous membrane on the side affected and the frequent escape of watery fluid from the nose. He was not aware of this until the fluid trickled over the upper lip and down the chin. He was made comfortable by the insertion of small wads of absorbent cotton into the nostril, from time to time, and this annoying condition gradually subsided. It is now thirteen months since the injection was made, and he has remained free from pain.

Case VIII.—April 17, 1909. Man, aged 33. Tic douloureux affecting left middle branch. Duration two years. Numerous attacks daily, three or more at night. The paroxysms last from two minutes to half an hour. Usual hyperesthesia of face. All teeth had been extracted from the left upper jaw without relief. April 24, injection into infraorbital foramen. May 1, pain in course of supraorbital nerve; injection at supraorbital foramen. Complete cessation of all pain until June 5, when pain returned in left upper alveolar process. Attack every fifteen minutes. Infraorbital injection given. He remained well for nearly six months. The next injection was followed by relief until January 29, 1910, when attacks recurred. Injection into infraorbital foramen. No pain since.

Case IX.—April 18, 1909. Man, aged 45. Right middle branch affected. Duration three years. All molars in right upper jaw extracted. Usual hyperesthesia. One year ago he was under my care for several months and the pain was relieved by abstinence from alcoholics, the administration of castor oil, and increasing doses of strychnine. Pain returned a few months ago. Attack about every five minutes, induced by the slightest touch on face. Injection at infraorbital foramen. May 2, after first injection had no pain for forty-eight hours; now eats without difficulty; very slight pain since. Deep injection into infraorbital foramen followed by complete analgesia in distribution of second branch. Jan. 23, 1910, reports complete relief for eight months. Pain returned about two weeks ago, confined to middle branch. Infraorbital injection. No pain since.

Case X.—May 11, 1909. Woman, aged 57. Tic douloureux affecting left third branch, and involving the tongue. Duration two years. Twenty to forty attacks daily in the last two months, preventing sleep. Paroxysm induced by mastication, swallowing or talking. Hyperesthesia of face. All teeth extracted from the left upper jaw. Injection for the third branch on the 13th and four more during the next two weeks. The pain was very much relieved, and she could sleep and eat well. She remained quite comfortable until July 14 when pain returned, but in milder degree. Injection was given at foramen ovale, and she remained free from pain for three months. Then, slight recurrence. Last injection Nov. 16, 1909. No pain since.

Case XI.—Nov. 6, 1909. Man, aged 55. Third branch on right side affected. Duration fifteen months. Pain circumscribed to the alveolar process of the right inferior maxilla. Pain almost continuous during the last two months, and accompanied by facial spasm. Prevents sleep. Exquisite hyperesthesia. Local injections of alcohol and various minor surgical methods had been tried without benefit. Injection at foramen ovale was followed by some analgesia in the lower lip. Pain subsided for 24 hours and injection was repeated. This resulted in complete relief for 48 hours, the pain re-

turning in a very mild form. On Nov. 23 injection was followed by analgesia in the lower lip and the lateral aspect of the tongue. No pain for two months. Still complains of numbness. Injection repeated and he remained well for nearly two months. March 19, 1910. Recurrence. Injection followed by analgesia.

Case XII.—Dec. 16, 1910. Man, aged 50. Twelve years ago neuralgia of the second branch on the left side. He was treated with strychnine injections in increasing doses and remained well for two years. Occasional pain since. One year ago pain returned in the second branch. He is unable to talk or masticate without inducing an attack. Almost continuous pain prevents sleep. Cutaneous hyperesthesia of face. At times, the third branch is involved and the pain extends to the tongue. Attack occurs about every five minutes. Injection into infraorbital foramen. Jan. 8, 1910. Pain continues in third branch. Injection at foramen ovale followed by relief, but pain having returned in the second branch, the infraorbital foramen was injected. At the end of a week pain returned in the third branch. Injection given for third branch, and three days later, the foramen rotundum was injected. He remained well for four weeks, when another deep injection for the second branch was given. This was repeated February 11. No pain since.

Case XIII.—Feb. 10, 1910. Woman, aged 66. Neuralgia began about fifteen years ago, affecting the left third branch. It ceased spontaneously for several months and returned at intervals. One year ago, it became more severe and persistent. Last two weeks, pain day and night. Relieved by large doses of morphine. Pain confined to the left third branch. Attack induced by the slightest touch. Extremely sensitive point over the left lower alveolar process. Many teeth have been extracted without benefit. She is unable to masticate and has difficulty and pain in swallowing. Has chronic bronchitis. Injection at foramen ovale. Analgesia followed, so that the face and alveolar process could be handled with impunity. Pain relieved. Three days later the injection was repeated and she has had no pain since.

Case XIV.—Feb. 17, 1910. Man, 40. Fifteen years ago pain in the right supra- and infraorbital distribution for three months. Gradually got worse. Five years ago pain almost constant for one year. Paroxysms every few minutes. Four years ago resection of supra- and infraorbital nerves. Slight relief followed, the pain continued in a mild form until, four months ago, when it became as bad as ever. Now involves the second and third branches. Attack every fifteen minutes, accompanied by spasm. Unable to eat solid food. Usual hyperesthesia of face. As a result of the former operation there are hypalgesic areas in the distribution of the nerves resected. Feb. 19. Injection at foramen rotundum and five days later this was repeated. No pain since.

Case XV.—Feb. 18, 1910. Woman, aged 50. Left third branch affected. Duration fifteen years. After freedom from pain for about six months it returned 18 months ago with renewed severity. Pain in third branch, at times extending to second branch. Paroxysm every two or three hours lasting five to ten minutes. Occasionally the pain radiates over the neck and shoulder. No spasm. Attack induced by mastication, swallowing or blowing the nose. No tender points. Injection for third branch followed by analgesia. March 2. Still has slight pain in second branch. Injection into infraorbital foramen. No pain since.

Sterilization of the skin and instruments is a *sine qua non*. The pain produced by the puncture of the needle is so much less than the excruciating pain that the patient is accustomed to suffer, that general or local anesthesia is unnecessary. The region of the foramen ovale is reached much easier than that of the foramen rotundum. In the latter the passage of the needle may be obstructed by a projecting coronoid process. It may also be difficult to accurately reach the desired point, owing to some unusual configuration of the skull. *X*-ray pictures have not yet satisfactorily shown the relationship of the coronoid process and the zygoma. Hence, the needle must be guided by the sense of touch and a knowledge of the anatomy of the parts. From two to three cubic centimeters of 80 to 90 per cent sterile alcohol are injected. There is no advantage to the patient from the addition of cocaine or chloroform to the solution, therefore, I invariably use the alcohol alone. When the solution has been accurately placed, analgesia soon develops in the peripheral distribution of the corresponding nerve. Even when this is not accomplished the pain may subside. However, when such reaction occurs, one may confidently assume that relief is assured. It may be necessary to repeat the injections several times in the course of a few days or weeks, according to the reaction. No serious accidents or complications have been recorded. Slight ecchymosis or swelling of the face sometimes follows the injection but disappears in a few days. Some rigidity of the muscles around the temporomaxillary articulation occasionally occurs after the injection into the region of the foramen ovale, but it usually subsides in the course of a week. Injection into the inferior dental foramen, is, however, commonly followed by muscular rigidity particularly of the masseter, which prevents the patient from opening the mouth, and may persist for a number of weeks or months. Recurrence of pain may take place from four weeks to fourteen months. The treatment is then repeated. The effects are usually more lasting after several injections, but, as a rule, patients are unwilling to have them repeated unless the pain returns. In some instances reported by others, the injections have not proved successful in curing the patient either because the needle did not reach the proper location on account of some anomalous conformation of the skull, or the patient refused to submit to a repetition of the injection. Again, in some cases of long duration, a psychosis is developed in addition to the neurosis, the patient still having a fixed idea as to the continuance of the pain, although the area injected is completely analgetic.

This form of treatment when successfully applied is virtually surgical nerve resection without the resulting scar. There is no good reason to-day, with the evidence before us, why a patient should be subjected to a cutting operation, when the alcohol injection is equally, if not more, efficacious in the majority of cases. Despite the brilliant results from this therapeutic measure recorded by many competent observers, nerve resection and intracranial division of the sensory roots are still recommended and practised under the same conditions as heretofore. Gasserectomy with its attendant dangers and mortality has always been considered a *dernier ressort*. Why should it not be considered so to-day? Yet, there are surgeons who unhesitatingly operate

without a fair trial of the alcohol injection treatment.

I take pleasure in expressing thanks to my friend, Prof. Irving S. Haynes of Cornell Medical College, for his courtesy in placing abundant anatomical material at my disposal during my preliminary work in this field.

145 West Seventy-seventh Street.

THE QUESTION OF HYSTERICAL FEVER.

By LOUIS A. LEVISON, M.D.,

TOLEDO, OHIO.

A large part of the literature on hysterical fever has an historical value only. The earlier writers took no temperature, making all observations on fever by other methods than thermometric measurements. As one reviews the literature, it is not easy to understand from our present-day point of view, how so many diverse and various conditions, so palpably organic in their nature, could be ascribed to hysteria. One can not refrain from musing over the possibility of future writers so commenting on our works of to-day. In the main the value of the journalistic references to hysterical fever is in indirect proportion to their age. The term, idiopathic fever, could equally well have been applied to many of the older cases. Given a patient with an unexplainable rise in temperature, the term hysterical fever was too often applied. The diagnosis of hysteria or other neurotic or functional disorder is essentially by exclusion. We are never justified in calling fever or other symptoms hysterical in the presence of yet unused diagnostic resources. Newer and better diagnostic methods are being devised constantly and the standard of today is not that of yesterday or to-morrow. The trend of modern medicine is materialistic. More and more of the phenomena which we have been pleased to term idiopathic, cryptogenetic, or functional, are being assigned their proper place in the classification of disease. Few of the reported cases of hysterical fever can stand the light of modern medicine. True, some of them are not to be explained from the data given, and the diagnosis of hysterical fever may be tempting. The question of hysterical fever revolves around the possibility of fever being produced by purely psychic phenomena with the exclusion of organic changes or toxic or chemical influences. Even when such changes or influences can not be demonstrated by the methods of to-day, they may stand revealed by the methods of to-morrow.

The riddle of fever remains unanswered. The number of etiological factors which may produce or be associated with fever are legion. Some are marked and well understood organic changes, while others are bacteriological and chemical toxins without demonstrable organic change. Fever is usually attributed to an excessive oxidation of the tissues, notwithstanding the fact that conclusive proof is lacking of an increased oxygen intake and an increased carbon dioxide output. The opinion is held by Woods Hutchinson that there are toxins present in fever which prevent the normal body metabolism, this perversion leading to the production of heat as a waste product. Ordinarily, the expenditure of energy in normal metabolism is constructive and promotes motion, secretion, and growth. In fever, the constructive processes change to destructive, Hutchinson holds, further, that the harm done in febrile conditions is due to the toxins, rather than the fever. The question is brought up whether the elevation in temperature may not be protective in its nature. It is well known clinically that certain severe types of sepsis may be associated with a subnormal temperature. Aronsohn[1] contends that the excessive temperature in febrile conditions is generated in the muscles. He speaks of the "living strength of the biogen being transformed into heat." This theory necessitates as a premise the presence of heat centers located in the brain, from which centers, caloric or trophic nerves control the generation of heat. The production of a rise in temperature by protein injection, as has been shown by Vaughan, Wheeler, and Gidley, is an important contribution. They maintain that fever results when the sensitized animal body begins to split up the foreign proteins which have been introduced into the body fluids. They think it probable that the sensitization is due to a specific ferment.

The presence of special heat centers and nerves has long been believed. Physiologists have endeavored to demonstrate such nervous structures, separate from motor, secretory, and other nerves. A very large number of experimental facts can be brought forth, showing the connection between the central nervous system and the body temperature, but conclusive demonstration of the heat mechanism is not forthcoming. Bernard believed that he had discovered such nerves in the cervical sympathetic fibers, but this was not confirmed. Injury to the brain, such as section or puncture at the point of juncture of medulla and pons, may cause a rise in body temperature. On the contrary, section of the cervical cord usually results in a drop in the temperature. The production of a rise in temperature by the experimental "heat puncture" is a classical procedure and demonstrates the possibility of fever from cerebral lesions. This puncture is made by thrusting the needle into the brain in such a manner as to pierce the mesial edge of the corpus striatum. It is stated by Tigerstedt that the rise in temperature from this procedure may amount to more than 3.6° F. The rise is due, not to a destruction of tissue, but to stimulation. However, heat centers have been variously located in other parts of the central nervous system, among them the septum lucidum, midbrain, cortex, and Reichert places them in the anterior horn of the spinal gray matter. It has been suggested by Howell that heat production may be controlled, not by a special heat regulating apparatus composed of thermogenic centers and nerves, but by the "coordination of the activities of various nerve centers."

Instances of a rise in temperature following injury to the central nervous system are numerous. It is to be regretted that reports on this point are not always clear. Not only is it impossible to exclude infections in many of the reported cases, but in carefully studied cases with all possibilities kept in mind, it may be virtually impossible to differentiate between organic changes, toxic, chemical, or other influences. Fever from tumors of the central nervous system is known. Here, the differentiation between cancer or other toxins and disturbance of a heat-regulating apparatus as the cause of the fever will be difficult or impossible.

The question of hysterical fever is one concerning which there is no unanimity of opinion. There is a general tendency to ignore or deny its existence, but many skeptics have changed their belief following puzzling cases. The usual symptoms of

hysteria very often appear spontaneously, that is, they require no definite predisposing illness, accident, or condition. Hysterical fever, on the contrary, if we may judge from many reported cases, has required a definite predisposing cause. The fact that some such predisposing cause has so often existed tends to cloud these cases. How can we be sure that there is no infection or other agent concerned? Some of the conditions mentioned in case reports as preceding or existing during the continuance of the fever are epileptic attacks, the puerperium, diarrhea, cramps, neuralgia, asthma, menstrual disturbances (common), ovarian tenderness, convulsions, dyspnea, articular rheumatism, chronic endocarditis, mitral and aortic lesions, hypertrophy and dilatation of heart, pulmonary edema, constipation, diarrhea, and enlarged spleen, gonorrhea, postoperative conditions, otorrhea, operation for gastric ulcer, pseudophthisis with dulness over lung, catarrh of lungs, autointoxication, purpuric rash, and others. To say that the presence of almost any of the above conditions is sufficient to cast suspicion on the hysterical nature of the case, would not be too much. The presence of certain of the above conditions discredits the report at once, and is either a sad commentary on the accuracy of medical observation or a mistaken conception of the term hysteria. In addition to the above there is a considerable number of case reports, in which is mentioned no condition, inflammatory or otherwise, that would directly militate against an hysterical origin of the fever. However, in medical reports, sins of omission are as grievous as sins of commission, and it must needs be said that such sins are not wanting.

This paper does not deal with those cases of so-called hysterical fever, in which willful deception on the part of the patient has played a part. Many of the reported cases of hysterical fever belong to this category. Likewise, the cases in which the temperature rose to an unusually high degree may be questioned. Alexander[2] reports the case of a girl, age 22, having attacks of dymenorrhea and convulsions, in whom the temperature rose every afternoon to 110° F. for four days. On the fifth day, the thermometer was placed under the arm and the mercury rose to the top (112° F.) and broke the instrument. Another thermometer registered up to 116° F. (the top) and was likewise shattered. No adequate explanation could be determined and it was called hysterical. Dr. Alexander Smith (quoted by Thompson) refers to a "case reported by a gentleman of high authority, in which the temperature of a male patient rose to 122° F." Another case was reported at a meeting of the Association of American Physicians, in which the temperature was said to have reached 148° F. Thompson styles the possessor of this startling temperature an "arrant knave and malingerer." In discussing the coagulation time of proteins, Thompson names three globulins coagulating below 148° F. These are paramyosinogen (116.6° F.), myosinogen (132.8° F.), and myoglobulin (145.4° F.) Kühne states that there is an albuminate in muscle with a coagulation point at 116.6° F. It is evident that these high temperatures are quite inconsistent with physiologic facts and have their origin in deception only. The methods of deception are often unknown, but most of them have been perpetrated with old-styled thermometers.

It is difficult to set an arbitrary temperature point at which recovery is improbable. There are well authenticated cases of tetanus, insolation, and other conditions, in which the temperature has reached 112° F. to 115° F. Recovery has occurred in some, more particularly the cases of insolation. The literature on hysterical fever contains numerous instances of unusually high temperatures. Among these may be mentioned the cases of Teabe 122° F.[3], S. Mackenzie 119.8° F., Philipson 115.7° F., Ormerod 115.7° F., Meissen 113.9° F.,[4] Lumbroso 113.3° F.,[5] Tillman 113.9° F.,[6] Vizioli 113.° F., Lorentzen 112.8° F.,[7] Sachs 111.2° F., Sciamanna 111.2° F., and Soulier 111.2° F.[8]

Hysterical fever is not a clinical entity, so no disease picture can be drawn of the condition. It is essentially but one symptom observed in the course of hysteria. It is difficult to depict an accurate description of the various conditions described under the name hysterical fever for several reasons. One is that many reports are manifestly descriptions of conditions not hysterical and may be reasonably judged to be typhoid, meningitis, chronic endocarditis, chronic peritonitis, epilepsy, pelvic disorders, autointoxication, traumatic conditions, tuberculosis, and others. Again, the less objectionable cases show no unanimity of symptomatology.

The condition seems to occur in females from fifteen to twenty times as commonly as in males. The average age of these females is about twenty-two. The larger number have been unmarried. Marked hysteria is mentioned as existing in many cases, in others there are hysterical stigmata, others are termed neurotic, traumatic or emotional shock preceded the fever in some instances, and there is a lesser number who have a negative personal and family history, in so far as neuroses are concerned.

The fever is in the highest degree variable. Its duration has been from hours to a year or more. Its intensity varies from hysterical fever without fever at all (*Scheinfieber*) to the startling heights mentioned above. If there is anything characteristic in the type, it is that the fever is irregular, paroxysmal, appearing on slight irritation and apparently independent of all other symptomatic manifestations. In some cases, it has been continuous, as in Lannois' case,[9] where the fever was not absent more than 48 hours during a period of seven months. In another case of the same writer, the fever was present for one year. This case was associated with intractable vomiting, hematuria, and albuminuria, so its hysterical nature may not be entirely above doubt. Sudden drops from 104° F. to 105° F., to normal without apparent cause has suggested hysteria to some authors. Other writers dwell on a temperature curve which is high in the evening, but regularly dropping 1° to 4° F. in the morning. The reverse of this has been present in other reported cases. Debove, whose name is conspicuous in the literature of hysterical fever, calls attention to the irregularity of the fever, its duration and intensity and the lack of an evening exacerbation. On the whole, a characteristic temperature curve in hysterical fever is not forthcoming.

There are a number of instances cited by Sarbo,[10] Preston,[11] and Wunderlich,[12] in which the temperature upon the two halves of the body was unequal. The determination of this point must depend on axillary measurements, as obviously, the mouth or rectal temperature cannot be utilized. Slight variations in axillary temperature could be easily produced by various conditions not dependent on the degree of internal warmth, so a considerable degree of caution must needs be em-

ployed in reaching conclusions on this point. In Wunderlich's case, there was a difference on the two sides of 1.5° C. for a year. The temperature was taken in the axilla, Holzapfel in discussing this difference, states that he made a large number of observations on normal individuals to determine the relative temperatures. In his series, there was an average difference of more than 1° F. (0.6° C.) on the two sides. Relative differences have been found in organic lesions, especially cerebral hemorrhages, but the date on this point is insufficient to judge of its value, either in hysteria or normal individuals.

The pulse in hysterical fever is usually increased in rate. However, a number of writers insist on the absence of relationship between the raised temperature and the pulse and respiration. The latter two may be quite unchanged in the presence of a considerable degree of fever. The reverse is sometimes met in the "scheinfieber" of the Germans.

Further than the temperature, pulse, and respiration, the clinical picture of hysterical fever varies with the condition it stimulates. It has been truly said that hysteria loves the paradoxical. To attempt a résumé of the symptomatology of the reported cases would be baffling, both through its immensity and diversity. The symptom-complex of typhoid fever may be traced in cases showing anorexia, coated tongue, diarrhea, headache, general malaise, flushed face, scaly and cracked lips, abdominal sensitiveness, and borborygmi. One writer states that his case of hysterical fever had pea soup-like diarrhea and an enlarged spleen. A large group of cases is associated with ovarian tenderness and pain, dysmenorrhea, cessation of menses and various types of abdominal pain. One case had the "inner genital organs" removed for a gonorrheal infection. Recurrences of cramps and fever, more particularly at the menstrual periods, suggested hysteria, inasmuch as bimanual palpation showed no infiltration of the operative stump. In another case, the author thought it not improbable that some of the symptoms originated in a slight hemorrhage into the cortex of the ovary. This association of hysterical fever and disorders of the female pelvis is striking. However, our present conception of the manifold pathological states of the female genitalia shatters the hysterical nature of many of the cases reported.

Clinical pictures simulating tuberculosis are often seen in case reports. These may vary from the pseudophthisis and hysterical lung congestion of Fabre[13] with fever, hemorrhage, dullness at apex, and cough to the suggestive afternoon rise in temperature only. Intermittent fever and chills in some cases suggest malaria. Pseudomeningitis is often described, especially by the French writers (Boissard, Chantemesse, Dalché, Reynard, Macé). A few cases with urticaria suggests an intestinal autointoxication.

Manifest hysteria is evident in a large number of cases. Among the symptoms and signs given in reports may be mentioned vasomotor disturbances, facile suggestibility, psychic disorders, as thenia, polyuria, anuria, retention of urine, chromatopsia, contracted visual field, tetany, increased irritability, tremor, convulsions, tachycardia, anesthetic areas, erotism, simulation, unstable emotions, with many others.

The absence of any nutritional disturbance or loss of weight in hysterical fever challenges our attention at once. Possibly most clinicians can recall cases of organic disease with a more or less continued elevation in temperature running for weeks or months without apparent or actual loss of weight. The writer recalls such cases in chronic tuberculosis, syphilis of the liver, and chronic endocarditis. The mere absence, therefore, of nutritional disturbance is not sufficient to rule out an organic lesion. This absence of tissue change and nutritional disturbance has been widely commented on by various writers, including Raffaele, Preston, Boulay, Caramino, Sarbo, and others, but not always in a critical manner It seems to be one of those conditions, which have gained momentum in the transmission by quotation. Bound up with the question of nutritional change is the experimental evidence concerning the metabolic activities of the body. It is not to be expected that many accurate, chemical estimations have been made in this field. This is true, because most of the case reports are not of recent date and owing to the faulty clinical observations and deductions noted. Cuzin[14] examined the urine of his case twice and found a diminished uric acid excretion. He calls this "urine nerveuse," an expression not infrequently met in the French literature. Sarbo states that one of his cases showed an increased excretion of urea. In the case of Naline Taidelli,[15] a young girl who had been having attacks of nervous fever for two years, showed no increase of urea or total nitrogen. It should be stated, however, that the figures in this case are not given.

The purest example of a rise in temperature due to neurotic, psychic, or hysterical influences would seem to be that produced by suggestion or hypnosis. If this is possible, it must be fairly conceded that hysterical fever is not a myth. If an organically sound individual, however impressionable he may be, can be compelled by suggestion, either auto or extraneous, or by hypnosis, to show a rise in temperature (fever) where none was before, then the controversy waged over the existence of this manifestation of hysteria must end. Most writers are silent on this point. Debove cites the case of a female, aged 24, with a temperature running between 102° F. and 104° F., where the mere mention of the somnambulistic state would sometimes cause the temperature to rise 1° to 2° F. He states, further,[16] that he has raised the temperature 2° to 7° F. by suggestion in the hypnotic state. Preston[11] states that he has raised the body temperature 1° F. by nonhypnotic suggestion. Krafft-Ebing,[17 18] states that he has raised the temperature by suggestion to 106.7° F. (41.5° C.). Èstèves[19] gives intellectual fatigue and intense grief as causes of hysterical fever. These latter two causes are psychic in their nature and must rank with suggestion. Doubtless, this fever, due to intense grief as depicted by Èstèves, is the scientific explanation of the mysterious and convenient attacks of "brain fever" following the climax or dénouement of many tragedies in romance. I have had several competent exponents of psychotherapeutics endeavor to raise the temperature by suggestion, but these experiments have always been unsuccessful, even with impressionable individuals, who were easily placed in a semihypnotic state.

The attention of the writer was attracted, particularly, to the subject of hysterical fever in its relation to tuberculin reactions. It is often necessary to explain minutely the possibilities and features of a tuberculin reaction to patients before the injection is made. This matter is of real importance in dealing with nervous or hysterical individuals and

phthisiophobiacs. The constitutional symptoms and accentuation of physical signs in certain reactions may be poorly developed and reliance may have to be placed in large part on the temperature curve. If fever can be produced by suggestion, emotional influences, or anticipation as recorded above, then the interpretation of tuberculin reactions should be carefully made. Out of a large series of diagnostic injections of tuberculin given by the writer, there have been a number in which the fever was the only discernible evidence of a positive reaction. However, not any of these have been considered hysterical, even in the presence of marked neuroses. The case of Fürst[20] is much quoted in this connection. His patient was a man of twenty-nine with a negative hereditary history. Six months before, there had been a fall resulting in the fracture of five or six ribs. Since that time, the patient had pain, cough, expectoration without bacilli, and inability to work. A light diffuse catarrh was determined and the usual temperature was 100.4° F. Following an injection of 0.5 mg. old tuberculin, there was a temperature of 101.3° F. with peculiar associated symptoms (*Nebenerscheinungen*). An injection of distilled water was given and the temperature recorded as 100.6° F. (38.1° C.) with the same symptoms. Three further injections of water were given, and each time the temperature became lower, and the last time, normal. This clinical observation was made ten years ago when tuberculin diagnosis was young. Such fractional variations in temperature hardly justify any conclusions, but, nevertheless, this case has gone the rounds, as a warning to diagnosticians to beware of an hysterical reaction to tuberculin.

The clinical condition known as pseudohysterical fever has not received as much attention as the febrile form. It is described at length by Sarbo, and also by Rosenthal, Heubner, and others. The usual ratio between fever and the pulse and respiration is reversed here, in that the two latter increase in rate, and not the former. The syndrome includes tachycardia, vasomotor disturbances, red skin, headache, thirst, malaise but the temperature remains unchanged. The similarity of this condition to a febrile disorder has not impressed, apparently, English or American writers.

Writers on hysterical fever have divided themselves into two camps, those who believe in and those who oppose the existence of such a form of fever. The observation has often been made that the skeptics are those who have never had a case. Many writers confess that they had always doubted the existence of such a form of fever, until confronted by examples, which were above criticism. It must be admitted that a few of the cases show no palpable flaw. Thus, Römheld states that one of his patients, who was hysterical, went through a railroad accident. Following this, the slightest irritation produced chills and fever, sometimes reaching 104° F. No cause could be determined and these febrile manifestations continued until the supervention of a pregnancy, when all symptoms permanently disappeared. Among those who believe in the existence of hysterical fever are v. Krafft-Ebing, Briand, Gagey, Sarbo, Ughetti, Wunderlich, Hale-White and a great many others. Opposed to it stand v. Stümpell, Grisolle, Landouzy, Pinard, M. Rosenthal, Jolly, and Schultze. The French authors were the first to speak of and describe hysterical fever, but these earlier writers, Pomme, Tissot, Baillou, and Rivière, interest us from an historical standpoint only, because they took no temperatures. Briquet in 1859 stated that he had seen twenty women with hysterical fever, with many and various symptoms, which he did not believe to be typhoid, meningitis, etc., because none of them died. This method of differential diagnosis ranks with that of another writer, who ruled out organic disorder because the fever did not respond to antipyretic remedies.

The relative number of Italian writers on this subject is not without a possible significance. We would expect a larger number, relatively, of hysterical patients in the Latin races, but the wide prevalence of malaria, especially the more chronic forms, in Italy may have caused some confusion in the differential diagnosis. The presence of the plasmodium malariæ of Laveran was unsuspected in the time when most of the Italian reports were published and no blood examinations were made for this organism. One or more writers mention the failure of quinine to reduce the fever as proof of its nonmalarial nature. This is entirely unjustified, as many chronic cases are very resistant to quinine. This possible error is given probability by Pucci, who states that hysterical fever is often uotidian, tertian, or intermittent.

To summarize, it may be stated:

1. That the earlier reports on hysterical fever are unreliable.
2. The larger number of case reports are faulty, in that the differential diagnosis from tuberculosis, malaria, typhoid, meningitis, peritonitis, and other infections, have been insufficiently considered.
3. The Latin races have furnished the greater number of cases.
4. Most cases have been in young women.
5. Medical opinion is divided on the question of hysterical fever.
6. The case reports of fever reaching an unusually high point may be set down as clever deceptions.
7. The fever has been more often variable in the highest degree, without definite relation to pulse and respiration.
8. The temperature has been found at times unequal on the two halves of the body.
9. Medical writers of high repute have reported elevations of temperature from psychic influences only, as suggestion or hypnotism. This seems to stamp hysterical fever as genuine.

A CASE OF ANGIONEUROTIC EDEMA.

By A. D. ROCKWELL, M.D.,

NEW YORK.

NEUROLOGIST AND ELECTROTHERAPEUTIST TO THE FLUSHING HOSPITAL.

The symptoms of angioneurotic edema are so well defined that the nature of the disease ought to be self-evident, yet it is my experience and the experience perhaps of all who have seen a number of these cases that they are far from being generally and readily recognized. Relatively, the disease is so infrequent that many practitioners have never met with a case and therefore it is not altogether strange that it should often go unrecognized and be regarded simply as a puzzling proposition.

During the past year three such cases have come under my observation, and consulting my records of years ago I find a number of cases, not fully recognized then, but now seen to be true types of this somewhat rare and strange disease. The following case would seem to bear out the statement that the disease not infrequently passes unrecognized, for of the several physicians consulted while the patient was abroad where the symptoms first became evident, as well as the family physician at home, all expressed doubts as to its nature and failed to give it a name. Two other reasons induce me to record this case, the first being the statement that "cold, which is an important factor in certain cases of urticaria, does not seem to play any part in angioneurotic edema, and that the season makes no special difference."* In this case, on the contrary, cold was the only important exciting factor, while the seasons made every difference in the world.

Another reason for recording the case is because of the very positive benefit derived from certain physical methods of treatment. The patient, a man aged 35, with a good heredity, and whose whole life had been one of healthful physical and mental activity, had been enjoying for several months a most delightful season of sightseeing abroad where the disease developed. One morning while in Munich, with the temperature down to 35° or 40°, the hands and especially the fingers began quite suddenly to swell, and soon the pressure of a ring on one of the fingers became so painful that it was necessary to have it filed off. In returning to this country he was still the picture of health, and on warm days and while in the house he felt no inconvenience, but a low temperature, and especially a cold wind, excited prompt swelling and a painful perversion of sensation in exposed parts.

A piece of ice held in the hand for a few moments caused, at first, a deep redness, followed by swelling and a perfectly white appearance. Rubbed over the mouth the same phenomenon was apparent, the lips swelling to double the normal size. The symptoms would then gradually subside, but it was some hours before the tissues became again natural.

A cold bath was intensely disagreeable because of the itching and general puffiness occasioned. Even the handling of the cold razor caused the finger tips to swell and itch. When he was out walking in the cold air, the hands, ears, and face must be protected in every precautionary way in order to give even halfway comfort.

There were no intestinal symptoms, but ice, and even ordinary cold water taken internally, produced decided gastric disturbance, due probably to edema of the wall of the stomach. The only predisposing causes were a somewhat nervous temperament and a pronounced business worry which came suddenly to him, while an exciting cause might be attributed to a temporary departure from his ordinary habit of moderate smoking and simple living. The total urine for twenty-four hours (thirty ounces only) was subjected to the nitrogen test, and in commenting on the result of the analysis Dr. T. W. Hastings wrote: "Judging from the creatinin output the total amount for twenty-four hours was not carefully collected, for the creatinin output is extremely low and almost impossible for an adult. The total nitrogen is likewise low, but might be accounted for by a carefully restricted nitrogen diet. The rest-nitrogen is higher than the average normal, and if the total urine for twenty-four hours is correct, this increase in the rest may be accounted for by the low nitrogen output. If the figure for the total amount of urine is correct, there is some disturbance of the nitrogen metabolism."

Notwithstanding the doubt here expressed as to the stated amount (thirty ounces) of urine passed in twenty-four hours, careful interrogation of the patient as well as various subsequent tests proved its correctness.

In considering this report and in attempting to apply therapeutic measures in accordance with it, I was impressed with the statement of Osler that "if the endogenous poisons, the result of perverted metabolism, anywhere from the moment the morsel of food is rolled round the tongue until its constituents have been through the furnace and are cast out as ashes and smoke, we talk a great deal, but we know nothing, so far, at least, as this disease is concerned."

Nevertheless, the results of the analysis seemed to favor the elimination of meat, and for one month the patient confined himself rigorously to a diet of bread and milk, but as at the end of that time there was not the slightest improvement, and the test was trying, he returned to his ordinary rational diet, eating in moderation anything he pleased, but abstaining from coffee and tobacco. Various drugs were used in a blind sort of a way, among them calcium lactate, for which something has been claimed, but without result. He was then subjected in an equally blind sort of way, perhaps, to various physical methods—electricity, vibration, phototherapy—the idea being to establish a healthy nutrition, and so obliterate the effective cause of the edema, about which we know so little. The results of these applications were not brilliant, but sufficiently marked to encourage a continuance of their use. It was instructive to observe that the application of light and heat, whether incandescent or arc, and which are so valuable in many vasomotor disturbances and in the relief of pain, did not agree with him, seeming to aggravate the symptoms.

On the other hand he reported amelioration of symptoms after the various electrical applications, whether static, high frequency, or general faradization. The galvanic current, however, seemed to serve a better purpose than any other method, and finally was wholly relied upon in the treatment, and under its influence there was not only amelioration but progressive improvement.

The patient is now and has been for many months almost entirely free from all disturbing symptoms, and the rather unusual rapidity of his recovery may fairly be attributed to the influence of these physical methods.

COCAINISM.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

Cocaine has a special action on the sensory centers and nerves, depressing their conductivity and diminishing or cutting off the transmission of impulses. It is a true analgesic. Its exact paralyzing action on the nerve centers and neurons is not clear, so that it must be studied largely from its effects.

There is no drug so fascinating in its perfect relief of discomfort, fatigue, mental worriment, and sense of exhaustion, and the impression which follows from its use is that of renewed vigor and unusual capacity, also that some new force has been added, or capacity for reasoning and observing of matters relating to the body and its surroundings.

Usually cocaine is given for states of depression, exhaustion, and many times for pain, both local and general. In states of catarrh, where the pain is accompanied with great discomfort, its action is very prominent and pleasing, and the sense of relief amounts to a positive conviction which leads to the renewal of the drug. This renewal must be continued, and very quickly an addiction follows in which an apparent normal condition is only obtained after the use of the drug. Unlike other drugs, there is a specific psychical action, carrying with it a profound sense of relief and vigor and good feeling. In the early stages this is prolonged, and fills the mind with satisfaction that is very impressive. Later, when the effects are shorter and less pronounced, the withdrawal of the drug is followed by intense gloom and mental bewilderment which craves a return of the effects. This first psychical effect of comfort impresses the organism so vividly that the memory of it is never forgotten. After the drug has been taken a long time, no depression or pain following its withdrawal can efface the memory of its first effects. Hence, perpetual struggle to secure the comforts which came from this first use. Aggravated catarrhs, irritating bronchial troubles, and states of exhaustion from starvation and poisoning are the conditions which cocaine relieves most markedly.

The first after effects following the withdrawal are of short duration, and not especially painful. Later this condition increases. The pain takes on a mental activity, a species of irritative melancholia and profound exhaustion which seeks relief at all times and under any circumstances. Nature seems to protest against the physical and psychical injury done in the most alarming way. This is seen in the facial agony of the cocaine taker when deprived of the drug. His sufferings are internal and not seen in muscular excitement. The profound change that follows its use in the quiet face, serene satisfaction, and perfect relief is evidence of its effects.

There appears to be a more pronounced susceptibility to this drug than to alcohol or opium. Very few cases are found in which the effects are unpleasant. Many persons become alarmed when they discover its tremendous fascinating effects, and make great efforts to escape. Those who are feebler may realize for a time its influence, but become powerless to escape by themselves. In their efforts to accomplish this they turn to morphia, spirits, and other drugs. A great many cocaine takers in this country are poisoned by spirits and drugs, and are exhausted before cocaine is taken, and the relief which this brings them is a new experience, increasing the degeneration.

Probably the largest number of cocaine takers among the lower classes belong to the ill-fed degenerate and poisoned classes. To them this drug is a revelation, and the rest of their lives is a perpetual struggle to secure it and enjoy its effects.

Its special narcotic action on the higher brain centers, meaning the ethical sense and morale of the man, is very marked. Criminality and lawless conduct are the natural results. The cocaine taker soon develops delusions of persecution, and becomes a criminal in his efforts to avert the danger which he imagines is confronting him from every side. In our experience, covering a quarter of a century and more, drugs and spirit takers who come to the institution with fire arms in their possession are always cocaine takers. No form of mental anesthesia or narcotism is followed by such pronounced delusions of death from violence and intrigue. This delusion may be concealed and covered up with great shrewdness, or be open and apparent. This constitutes the greatest danger, particularly of the lower classes who use this drug. They not only lose all ethical sense of law and order, but they become centers of intense suspicion of injury by others, and have no regard to any obstacles which prevent them from getting the drug.

Shrewd peddlers and disreputable men cater to this want, by furnishing the drug in the most secretive ways. The cocaine taker often exhibits a degree of criminal sharpness and superiority in his efforts to get the drug. If he is an alcohol or drug taker, the degeneration is so pronounced that any criminal act, regardless of consequences, will be undertaken to secure the drug.

Compared with the alcoholic, he may possess a degree of vigor that is misleading and only show his disease in the insane mania to possess the drug. The alcohol and drug taker may be cowardly and give way to circumstances, and show normal fears, but the cocaine taker has a maniacal boldness and reckless cunning when his interests are perilled and the drug is withdrawn. He will stoop to any crime, or any act that promises relief, regardless of what the results may be. The delusion of persecution is frequently associated with one of revenge, and desire to inflict injury for some real or imaginary insult. Often the presence of this particular phase of character is an unmistakable indication of his cocaine taking. The vindictive criminal in the lower circles who fights the officer seeking his arrest, who suddenly assaults people on the streets or shoots people without any provocation, or sets fire to buildings, commits serious damages, acts wildly and maniacally, is suffering from cocainism.

The alcoholic and the drug taker follow uniform lines of conduct that can be seen and anticipated to some degree. The cocaine addict is erratic, changeable, uncertain, always dangerous, and likely to be a criminal any moment. If his addiction is mixed up with alcohol and spirits, greater uncertainty follows. He is never suicidal, but always homicidal.

Cocainism among the intellectual classes is more concealed and is probably one of the most delusive addictions known. Many persons in professional circles begin with the use of cocaine to give them power and strength for certain particular acts or events. In literary circles many writers use cocaine and show it in their writings. A very interesting field of observation is in the smooth, flowing sentences of periodical and fiction writers, who do the work under the influence of cocaine. Both the brain and nervous system of the cocaine taker is lowered,

paralyzed, and starved. He is unable to reason clearly. Hence he is the most dangerous, because he cannot realize his own condition compared with the alcoholic and morphine taker, who in their lucid moments have some sense of their danger and possible defects of reasoning. He is a veritable dement. The exaltation of the ego and the delusions of strength cover up and conceal his real condition. In all probability the cocaine taker is more thoroughly insane than all other drug addicts, although it may not appear. His health may seemingly be about the same, and his anemic appearance and staring, suspicious eye are the only evidence of impaired health. Cocaine addiction is increasing, particularly among nervous, exhausted men and women and the half-starved degenerates of the lower walks of life.

Cocaine addiction can be concealed for some time, hence its peculiar danger. Certain general symptoms give indications of the use of cocaine, but its verification may be difficult. There is no more dangerous drug, although it is widely used and praised highly by many physicians. Like the germs of infectious diseases it must be introduced into the community, then it spreads from one to another. Possibly it may die out in its local growth, but not until a percentage of those who suffer from it have been destroyed. It is possible that physicians, by thoughtless prescriptions and telling the patient the character of the drug they give him, may start the use of the drug in the community. It is certain that proprietary drugs for local pains have been found extremely popular and have had a large sale, until the substance composing it was discovered. Then the drug was used alone. Druggists, physicians, and patent medicines are responsible for this new scourge of humanity. The remedy is to stop its sale, except for some specific purpose, to be noted on a public book, and, where a doctor uses it freely, there must be some accounting, so as to prevent its danger. In a mill town where catarrh was prevalent, a certain proprietary drug had an enormous sale. The board of health discovered that the drug contained cocaine. As there was no law that would apply in this particular instance, the greatest difficulty followed in suppressing its sale. This happened some years ago, but the result of that one drug, extended over a period of nearly two years, was the permanent ruin of at least a dozen persons, whose drug and spirit addiction followed them until death. Drinks served from the soda fountain, containing cocaine, are attracting increased attention by the sudden popularity and enormous sale in certain sections. When the fact is ascertained that their chief value consists in cocaine, in small quantities, efforts to suppress them are both difficult and doubtful. The proporietors, by merely changing the names, can continue the use, and, if the soda fountain dealers refuse to dispense them, they are frequently sold direct to the customers.

A great deal of attention was attracted by an instance which came under my care, in which several eminent physicians failed to make a satisfactory diagnosis. When the patient was brought to the hospital and the surroundings were changed, it was found that he depended on a certain proprietary drug, which contained cocaine, and that his condition was due to cocainism, with mild delirium at night and increasing delusions that were largely concealed. His recovery was rapid when the drug was removed. He remained abstinent for many years, but the fascination for the effects of this drug never died out. When wearied and worn the impulse to secure this drug was very strong with him, and could only be overcome by keeping away from all places where he was likely to get it.

In another case under my care a cocaine addict, realizing the danger from the resumption of the drug, turned to morphia for help, and after several years of the addiction of this later drug, took up cocaine again; breaking away from this, he became an alcoholic. Realizing his danger, he entered voluntarily into an insane asylum and remained there till his death. In criminal circles cocaine is occasionally used to give courage and serenity for criminal acts. A burglar declared that it was necessary to enable him to carry out his plans without flinching or losing his judgment. It has been noted that criminal suspects who show a remarkable steadiness of nerve and frankness of manner when subjected to adroit questions by detectives, are not infrequently under the influence of cocaine. An instance of this kind came to my attention, and it appeared to me that the suspected person believed what he stated, with the utmost confidence and frankness, although it was evidently false. The impression of innocence was so pronounced that he would have been discharged had not the authorities, at my suggestion, kept him in confinement for another day. Then an examination revealed the real man, and eventually he acknowledged his guilt. The cocaine had been exhausted, and the remarkable paralysis and control of his emotions and reason disappeared.

The ordinary cocaine taker is secretive and suspicious, particularly in the later stages, but all this is concealed and only apparent in his conduct, and in little things. Thus a man who was known to be in ill health manifested great interest in having the locks of his house changed, and burglar alarm wires put around the windows. This he explained in a very rational reasonable way, but why he should do it at this time when there was no particular occasion, attracted attention. It was found that he was a secret cocaine taker. In another instance a man wrote a number of wills at short intervals, and this very unusual act resulted in the discovery of his secret use of cocaine.

In doubtful cases it is always wise to consider the possibility of the use of this drug, for its manifestations are exceedingly variable and misleading. The increasing difficulty of procuring it in many of the States will, of course, diminish the number of cases.

Medical men can do very much in concealing its use to their patrons and dispensing it personally. The paranoic cases that are so bewildering are very likely to have a cocaine origin, and the strange unusual acts are all likely to be traced to this source. In all probability, this drug is much more widely used, both legitimately and otherwise, than is supposed. The fact that the sales are increasing is an unmistakable indication of this.

Tuberculosis and Malaria in Greece.—Consul-General George Horton has made a report from Athens on the conspicuous work of Greek physicians in combating the country's two chief scourges—malarial fever and tuberculosis. An annual average of 2,000 persons die each year from the former, while in epidemic years, due to excessive rains, the number exceeds 6,000, which was the case in 1905. The population of Greece is 2,433,806. The people have been interested through lectures, pamphlets, etc., to fight the malaria-carrying mosquito by draining stagnant ponds and throwing petroleum on them. A tuberculosis congress will be held in Athens next year, to which will be invited, not only physicians, but all the mayors and other prominent people of Greece.

MIGRAINE, PERIODICAL VOMITING, AND EPILEPSY, WITH REPORT OF A CASE OF PERIODICAL BLOODY VOMIT.

By OTTO LERCH, A.M., M.D., Ph.D.,

NEW ORLEANS.

PROFESSOR OF MEDICAL DIAGNOSIS, NEW ORLEANS POLYCLINIC.

It is interesting to compare the characteristic features of hemicrania, periodical vomiting, and the attacks of epilepsy. One finds the etiology of all to be practically identical, the pathology to be negative, the symptoms, though differing, to show resemblance, the prognosis to be unfavorable in all, and the treatment to be more or less the same. In fact, one gains the impression that migraine, periodical vomiting, and epilepsy represent varieties of one condition, affecting the brain and giving rise to symptoms more or less light or severe.

Migraine is usually inherited, and some cases may be traced through several generations. Occasionally it commences in early childhood, though the time of puberty seems to favor the onset. Sometimes it may commence later, though rarely after middle age. Emotion, excitement of some kind, a disturbed digestion, etc., may be the direct cause. The most important symptom, and often the only one, is the unilateral headache, with loss of appetite, nausea, and vomiting. The attack may last from a few hours to several days. Prodromal symptoms are not rare, such as general malaise, nervousness, depression, dizzines, pressure in the head, and spots before the eyes. The headache affects one side of the head, usually the left; it may alternate or affect other portions of the head occasionally. It commences mildly and gradually increases in intensity. The patient feels miserable, is nervous, depressed, complains of throbbing in the temples, and is highly sensitive to light and noise. The loss of appetite is complete, and in severe attacks the slightest motion increases pain, and even the sight or odor of food may produce a new vomiting spell, with severe pain in the pit of the stomach. A prolonged deep sleep often breaks up the paroxysm and the patient may wake up in perfect health. The attacks are periodical, and the intervals between them vary from a week to several months. In some cases the skin is cool, the temporals hard, and the pupils large; in others the face is reddened, the arteries soft, and the pupils small.

In the angiospastic and paralytic forms of the disease the attacks are occasionally accompanied by disturbance of sensation, motion, and speech; a peculiar scotome and floating spots before the eyes are frequent; amaurosis is rare. In one of my patients it appeared as an aura and lasted each time for several minutes. Incomplete aphasia and paresthesias of various kinds are not rare. Weakness in one arm or in one leg or a complete hemiparesis occurs; differences in the pupils have been recorded; and in one of my patients was a symptom which I have noticed in several patients, namely, ptosis of the right eyelid. Palpitation and marked cyanosis, especially of the lips, are a constant symptom. Occasionally slight psychic disturbances may be found accompanying the attack. Just as in epilepsy, so also in migraine there have been described spells of dizziness and of cardialgia taking the place of the paroxysm; I have also found in one patient states of excitation and partial blindness. One of my patients would come to me occasionally in a highly nervous condition, saying, "Doctor, to-day I am as blind as a bat, but have no headache." Gastroxynesis is supposed to be such an equivalent.

Periodical vomiting, first described by Leyden, often affects children and adults apparently in the best of health. The paroxysms occur at intervals of from one week to several months, and the attack may last from one to several days. General malaise, headache, and other symptoms, as emotion and excitement, may precede the attack. The paroxysm is characterized by intense nausea and copious vomiting of food, followed by mucus and bile, and accompanied by intense pain in the pit of the stomach radiating to the back. The patients are depressed, are sensitive to light and noise, and avoid motion, as this increases the pain and the attacks of vomiting. Loss of appetite is complete. The headache may be unilateral, though occasionally it affects the whole head. Not rarely the paroxysm is predicted to the day, and its length is usually typical.

One of the characteristic features of epilepsy is the heredity of the disease in a large proportion of cases. It can be traced in families, and often a neurotic inherited predisposition is found. No lesion has yet been discovered to explain the disease. Its pathology is negative as to the cause. In all cases the paroxysms, mild or severe, half-sided or involving the whole body, are separated by intervals of perfect health. Aura may precede the attack, and do so in many instances, such as a twitching of muscles, pain in the epigastrium or headache, spots before the eyes, amaurosis, seeing of color, hearing peculiar sounds, anxiety, nervousness, and other similar symptoms. The onset of the paroxysms is sudden, sometimes directly caused by indigestion, constipation, excitement, etc. The patient is attacked when in apparently perfect health. A sudden dizziness, palpitation, or slowing of the pulse, a sudden perspiration or flushing of the face, a sensation as if paralyzed, with complete inability to move, are considered epileptoid; whereas a sudden loss of consciousness, occurring without warning, lasting a few seconds and perhaps following an aura and accompanied by a few convulsive movements, a sudden cry, and a fall, may constitute the attack, the patient afterward continuing his scarcely interrupted work. The paroxysms of "grand mal" consists of an aura followed by tonic and clonic convulsions and coma. The equivalents of epilepsy are peculiar psychic conditions that may take the place of the attack. Cases of bloody periodical vomiting are rare, and are rarely mentioned in the textbooks. Hysteria, according to some, occasionally shows repetitions of this symptom during an attack, the amount of blood vomited usually being small.

The following cases are reported for illustration:

Case I.—Mrs. S., 48 years of age, born in Mississippi, the mother of five children, stated that her father was a healthy man and died at the age of 70 years. She did not remember her mother, who died during childbirth, when 37 years old. She had had scarlet fever and the usual diseases of childhood, but no other infectious disease. She remembered to have had severe attacks of unilateral headaches with nausea and vomiting since early childhood, which became more frequent and regular with the establishment of the menstruation. For the last twenty years she had had an attack each week, commencing on Wednesday and usually lasting three days. She always had been entirely free from attacks during her various pregnancies. With each year they had become more and more severe.

The attacks commenced with headache coming on at a time when the patient felt in perfect health; they were left-sided, and increased in intensity till they became unbearable and morphine had to be administered by injection in order to stop the excruciating pain. As the pain increased nausea commenced and copious and repeated vomiting spells followed. First the stomach was emptied of its contents, and large quantities of acid water, mucus, and bile followed, the vomiting being accompanied by intense pain in the epigastrium radiating to the back. For many years she had vomited blood in these attacks, varying in amount from a few tablespoonfuls to a cupful. I had an opportunity to observe two such paroxysms of bloody vomiting in two successive weeks. Gradually the severity of the symptoms decreased, and after two or three days she fell asleep and woke, weak but with appetite restored and apparently in good health. During the attack the patient was pale, cold, and clammy, and of a collapsed appearance; the abdomen was sunken and tender to the slightest touch, the extremities were cold, and the pulse was feeble and rapid, the arteries were contracted, and the urine dark in color and small in quantity. The patient was gracile, 5 feet 2½ inches tall, and weighed 103 pounds; had had white hair since the age of 25 years. The respiratory and circulatory organs were in perfect condition. The stomach was in the normal position and the contents, after a test meal, showed nothing abnormal. The urine was normal. Nothing abnormal was found in an examination of the abdomen. She had hysterical stigmata. The patient yielded readily to treatment, for the first time during the last twenty years has been free from attacks for three months at a time, and is still doing well.

Case II.—M., 8 years old, was a school girl. Her father was in good health, her mother, hysterical. She had had measles and chicken pox during the first years of her life. When 4 years old she contracted a cold, and with it an attack of severe nausea and vomiting. Since that time she had had these attacks regularly about once a month every winter, and occasionally in the summer. The paroxysms commenced as a rule with a cold, headache, and nausea followed by vomiting. The stomach contents were ejected and followed by large quantities of greenish sour liquid, mucus and bile. The loss of appetite was complete, and for days the smallest amount of food taken caused new spells of vomiting. The paroxysms lasted from four to five days. The temperature occasionally rose. The urine contained albumin. During the attack the child suffered intensely from the nausea and pain in the pit of the stomach. The face was pinched, the extremities cold and clammy, the arteries contracted, the pulse rapid, the abdomen sunken and painful on touch, and eyeballs protruded, especially the left. The exophthalmos and albuminuria lasted several days after the attack had passed. Sensitiveness to light and noise was excessive. The child was poorly nourished and nervous; the chest and abdominal organs were normal; the urine was free between attacks; the ears, nose, eyes, and throat were normal. The child has been free from attacks since November, 1908, when treatment was commenced.

The exophthalmos which accompanies the attack indicates intracranial venous hyperemia. The direct cause of the attacks may have been the swallowing of mucus during a cold.

Case III.—Mr. G., 58 years of age, born in Louisiana, a plantation manager. He did not use alcohol or tobacco. His mother died when 78 years of age. His father had been a very nervous man, and had suffered from migraine during his whole life. The patient stated that he had suffered from severe attacks of unilateral headache with nausea and vomiting since childhood, that the attacks had become more and more frequent and severe on the left side, and that excitement, especially anger, brought them on. The patient was of a nervous temperament; the chest organs were normal, the arteries sclerosed and tortuous. The stomach contents, after a test breakfast, showed nothing abnormal. The patient stated that he had been gray since the age of 17 years. No paroxysm since October, 1908. I have noticed frequently that these patients turn prematurely gray, probably due to a disturbed nutrition of the hair.

Case IV.—Mr. P., 33 years of age, born in Louisiana, had been chemist on a sugar plantation till 1901. The patient comes from an hysterical family, his organs are normal and his life is regular; he does not use alcohol or tobacco. In March, 1901, he was employed as a trainman, and while trying to put off a man from the train was shot, the ball crushing the skull above the right ear and glancing off. He was unconscious for a few minutes and woke up with difficulty in breathing, inability to speak, and complete left hemiplegia. From this he gradually recovered in the course of a few weeks, the bone having been entirely removed over an area the size of a quarter of a dollar. In October, 1901, he was employed as chemist, and it was then that he had his first attack of losing consciousness followed by convulsions. They were repeated every three months for two years, then they changed to attacks usually at 3 A. M., commencing with a groan or cry followed by tonic and clonic convulsions and coma. They became now more severe, and sometimes he would have four to five paroxysms one after another. A year later these paroxysms would alternate once a week with spells of insanity, as is usual in these cases of great violence, each lasting for several days, so that in June, 1904, he had to be confined to an asylum. It was then that the treatment as outlined later was commenced, and ever since he has been free from attacks and has made his living as a clerk.

Case V.—Miss B., 36 years of age, was a frail, nervous patient. She had always been nervous but in good health until ten years ago, when, after some trying work one night, she was taken with a severe paroxysm. The mother stated that she heard her cry, and hurrying to the bed, found her in convulsions and unconscious. This first paroxysm was followed by a large number during the first twenty-four hours. The next was six months later, at night, and since then she has had attacks with an interval of four to six weeks. They were preceded by a drifting sensation and twitching in the hands when coming on in the day time. Patient has a good family history, except that the mother is hysterical, and her organs are normal. Was first seen April, 1907, and has been free of attacks since.

Case VI.—Anna B., 12 years old, was an adopted child, nothing known of her parentage; had had attacks of genuine epilepsy since she was two years of age, a paroxysm every two months. She was mentally undeveloped. The organs were normal. There have been no attacks since the treatment was begun.

Case VII.—R. H., 20 years of age, a student. In December, 1907, he was struck on the right side of the head by one of his schoolmates with the foot during hazing, and had an epileptic attack three days later. Ever since that time he had had a paroxysm once a week, sometimes at night, sometimes during the day. There was no aura, the patient dropping to the ground without a sound, as if shot. The left arm and leg became rigid, followed by convulsions and coma. Operation was considered useless by a surgeon. Treatment was commenced three months ago, and he has been free from attacks since then.

One cannot fail to be struck by the resemblance of these diseases, as has been recognized in migraine and epilepsy. The heredity is a characteristic feature, and the search for a pathological lesion has been negative in all; symptoms of epilepsy point to a focus, and focal symptoms are occasionally present in migraine. An aura may precede the attacks, and excitement of some kind, as anger and fright, or digestive disturbances, may cause it directly. The onset is sudden in all, and the paroxysms are separated by intervals of apparently perfect health. It may be difficult to differentiate an attack of periodical vomiting, while migraine and paroxysms of epilepsy show resemblance. A prolonged and deep sleep usually closes an attack from which the patient awakes to apparently good health. The equivalents of migraine resemble those of epilepsy. With the absence of a lesion in the brain as a cause, it is difficult to find a satisfactory explanation of these conditions, and numerous have been the theories advanced, such as the theory of autointoxication, the "Strümpel" theory, "sudden removal of inhibitory influences, sudden discharge of stored-up motor impulses," and others. Vasomotor spasms have been thought to be the cause of migraine. The theory advanced by the writer in *American Medicine,* Vol. XI., No. 9, pages 312-15, is that the condition is due to a permanent instability of the brain, inherited or acquired, and a congestion brought about by various causes there stated. The paroxysms with convulsions and focal symptoms due to edema seem to explain the paroxysms of migraine and periodical vomiting as they seem to do those of epilepsy. Acting upon this theory, treatment of the general conditions of the patient has been carried out with special attention to the circulation with the means well known and understood. A bland, salt-free, vegetable and fruit and milk diet, withdrawal of all stimulants, mild purgation more thorough at the time of an expected attack, mild hydrotherapeutic measures, exercise and rest in proper proportions, and the administration of atropine, the bromides, and nitroglycerin as indicated, have succeeded in relieving a number of these patients.

Thanks are due to Dr. A. Fossier, who has assisted me in this work.

SPECIALISM IN MEDICINE; IS IT OVERDONE?*

By THOMAS J. HILLIS, M.D.,

NEW YORK.

It is not the purpose of the writer to go into the history of medical practice—trace it step by step through the centuries. He prefers to leave that to the medical historians, one of the ablest of whom has the honor to be a member of the Celtic Medical Society, one who delights to bask in the ancient literature of medical nomenclature.

The art of healing was respected and prized in the ages past and found expression in the temper and culture of the times. Farther back than the thirteenth century, it began to be recognized that the field of medicine was too wide to be grasped by any single hand, that in order to cultivate that field it was necessary to cut it up into sections to make it the more convenient, and its application the more certain. That was the hour the specialist sprang into activity. This activity, however, was arrested by periods of repose, but light there was, a dim light to be sure, but nevertheless increasing in candlepower until to-day, the twentieth century, when the light is dazzling, searching out the dark corners and exposing their contents to view, yes, piercing the human body and with fidelity photographing its interior, penetrating even masses of solid steel as if they were cobwebs.

The science of medicine has appropriated some of those discoveries and put into the hands of some of its professors those new weapons to know the use of which constitutes the physician, to be expert in the use of one constitutes the specialist. Now, in order for the individual to determine his expertness and adaptability in handling best some one of those several appliances, he must find out just which of the weapons is best adapted to his weight and reach, measure it as a skillful prize-fighter does his adversary facing him in the ring.

A great deal has been said about the time a student should devote to be accounted skillful in his specialty. Some say five, others ten years, working in the wider field of general practice and the particular branch that he recognizes as his forte should appeal to him as a heritage, a birthright, while treading the wine-press with the others in the larger vineyard. It is essential, though, that the man be possessed of a knowledge of the whole field—since the whole contains all its parts—to be the better able to determine any inequalities in a given part.

It is the opinion of the writer that no hard and fast rule can obtain in a matter so significant. Two men of unequal intelligence adopt a profession, the medical profession, a specialty. The less intelligent soon outstrips the other because he possesses a deftness of manipulation and adroitness in accomplishing that leaves no comparison between the two. He can do more and do it better in a given time than the more brilliant man. In other words, the plodder is on top. His genius for application sent him there, and often keeps him there to the disgust of his brilliant rival at the foot of the ladder looking Heavenward in vain. The man above has concentration and grasp. The man below is towering, overtopping in intellect, he has the material but cannot construct. The creations of his bright mind are utilized by the other fellow who knows how to build securely—he has climbed up the brilliant man's back to occupy his exalted position.

To specialize as approved by usage is to use the square and plumb, travel through a dark alley without hitting his head against a projecting brick from either side, breathe an atmosphere saturated with his own mode of procedure and reflecting his ambition, build with material often quarried by other hands than his, side-step responsibilities to be shared with others. In fear of slipping he carries a balance pole to better maintain his equilibrium, which shifts with the conditions that environ him.

*Read at a meeting of the Celtic Medical Society, February 24, 1910.

To accomplish his purpose it is meet he should be thus ready and he is.

No doubt this is why the specialist seeks an avenue of exit for the consequences of his intense application by betaking himself to other and pleasanter pursuits, indulging his fancy in a hobby, as teaching his favorite dog to dance, a goat to butt with neatness and despatch, a chantecler to crow with better grace and rhythm. Or, he may rise to a higher plane, trace a comet in its wanderings, tread the dark pathways of space in an effort to circumscribe the Universe, or weigh a distant sun. These hobbies are the safety valve that keep the specialist on the monorail of daily routine, the gyroscope that regulates his movements, clarifies his brain, and fits him for renewed and better effort.

The best specialists, as a rule, don't know how to write, writing is a sealed book to them. The art of writing is a specialty in itself and a great one—a thing often to which the most accomplished operator is a stranger. Often the man standing by gives valuable hints to the operator, while if he had the knife in his own hand it might go hard with the individual on the table. This sort of thing makes fine operators poor lecturers, the two qualities are seldom found in the same man. The downright failure in the operating room often turns his hand to writing—perhaps a text-book, something he has to tell the other fellows, things he has observed that have escaped their minds—that is, if they were ever there. But mind you, gentlemen, he will avoid stating that he was himself a failure in the art about which he preaches. He has written well, much better than he could operate, operating was not in his line and writing is.

The ambiguity and verbosity in most of the medical volumes on our shelves make them practically unreadable. This is largely due to the fact that the author wants to make a bigger book than the facts he has to present warrant. So he pads and stuffs and succeeds in spoiling his book and the temper of him who tries to read it.

He is the man of the hour in literature, any literature, who has something to say and knows how to say it. The unread author, as a rule, has attempted too much. He may know how to make a pair of shoes, but he cannot make that fact known in his book. Then, gentlemen, his specialty was making shoes not writing about them. To-day, the writer of a text-book, and a good one because he did not write it, is extolled for his perspicacity and clearness. The book is clear, you can see down in the deep water, thanks to a clever fellow who has no standing in the operating room, but whom the author in a moment of felicity or inspiration selected to do the work for which he himself was so illy fitted.

That gentleman was an operator not a writer. He did not commit the blunder of the shoemaker who tried to write about shoes. He was keen enough to recognize this in time to save himself the mortification of reading about his book in the medical journals which have lately come to grow tired in the monotony of condemnation, and cut stupid authors to pieces in their review of new books. Now, was he magnanimous enough to give due credit to the gentleman that set his compass and pointed the way when he was heading directly for Salt Creek?

It is not from numbers in the wide field of medicine that danger will come. The overdoneness will be in the man not his occupation. If his eye or mind or both be trained to look for a certain thing or effect, and for it only, it or something like it is very likely to appear. If the specialist be overtrained—trained too fine, hears imaginary sounds, examines everything big or little with a magnifying glass—a time comes when he is color blind, his spectrum is blurred, the lines impinge on each other, and he is sure to make mistakes in diagnosis and treatment, operate when not necessary, oftener than not operate when necessary.

It is an everyday occurrence with most of us while on our professional rounds to be bored or amused, as strikes our temperament, with fragments of gossip swapped by passengers at our elbows. Two ladies meet, the conversation proceeds. The one, after exhausting her magazine of invective against the design and proportions of her rival's hat, switches off with:

"How is your mother's cold?"

"Quite improved, thank you," replies the other, "but we were anxious, since a specialist discovered bacilli in her sputum. He said if we remained in the lowlands mother was doomed. We remained; the germs proved harmless."

"That's how it was with Aunt Betsey," said the former speaker. "Pa took her to a liver specialist. He said she had cancer. She went home to die but didn't. She is now at a tub of clothes. I must hurry my shopping as I want to help her with the ironing."

Those specialists were overtrained, if trained at all, and overtraining is as bad as undertraining—here extremes meet. Both beget carelessness which is the parent of ignorance and overconfidence. Reflection and repose are valuable adjuncts to the repertory of all, but most valuable, perhaps, to the professional man and specialist.

Then is specialism overdone? Hardly, the truism that "many hands make light work" holds in this case as in others. The work will not only be lighter, but it will be better done. In the industries this is well understood, so that it has come to be that a foundry, a factory, a dry-goods shop or department store has in its employ all the way from five to twenty-five departments, specialties. The supervisors of those departments are veritable specialists. It ensures better and more efficient service. The standard of efficiency, not numbers, is what tells in the final accounting. In the end a bungler will be more expensive than a better man.

This fact impresses itself upon the patient when if the incompetent do not improve in his methods he is relegated to the rear to be lost in the cloud of dust left behind by the men racing to the front. The temper of the hour is for maturer judgment and better technique. As the profession stands to-day it is quality not quantity that counts, but quantity and quality will harmonize, grow together, and prosper.

As to the bungler, he often waxes fat and flourishes like the green bay tree, but all the while he is in hiding behind a powerful patron, someone is standing between him and the results of his very inferior work. The pathologist knows about it, so does the undertaker. Neither will speak. The former is overwhelmed with the excellence, if not the beauty of his specimen, the latter chuckles over his great good fortune, while the elders weep and the ragged urchins gambol on the naked hearth.

The physician of to-day, specialist or not, particularly if he be a good one, who has a bishop for

a patron, has his professional future in his pocket. If, however, he have the great good luck to claim an archbishop, his path is strewn with flowers and the road to success is a triumphal march, not only for himself, but for the two or three favored youths who are fortunate enough to be accounted his assistants.

Then, again, there are times when there is not room at the top for merit, for the fellow with the lighter specific gravity has by a trick taken the big man's place, crowded him out as it were. He has come to the surface on the back of his patron who is an adept at this kind of swimming. Often the well-equipped and capable physician, be he specialist or not, is left at the bottom of the pool. He is handicapped by his own avoirdupois for the reason that he does not know how to manipulate—how to court success.

At present the activities of our arduous lives demand a greater nervous energy, a greater consumption of force—the thing necessary to keep us alive. The wear and tear is telling, and since an effort must be made to maintain a standard of efficiency, more men must needs be employed—specialists to handle the different and varied clinical material always on hand in the two or three hundred hospitals, public and private, in Greater New York. These numbers are constantly growing and the hospitals daily, like the sea, giving up their dead.

Why are the hospitals in existence? Simply to supply a want. Why do so many people die who go to the hospitals? Is it because they don't present themselves early enough to the clinician? Then do they die through their own want of thought or inclination in the matter rather than by incompetent hands? To-day there are at least four times the physicians per capita of the population that there were when some of us were young, and they have much to do.

Gentlemen of the Celtic Medical Society, is this army, the subjects of disease, to be permitted to go forward in its march of death? Happily, no; a way is being opened. It is the domain of preventative medicine, and now working with assiduity in that domain are the students of experimental science—with a view to prevent disease rather than to cure it. Here again the old saying has its charm as well as its significance, that "an ounce of prevention is worth a pound of cure." On this trite aphorism the whole superstructure of experimental and preventative medicine rests.

We would have thought of this before if we considered that it is easier to prevent an accident than repair a damage. The services of two watchmen in place of one will make the work more efficient, and certainly will leave less to do for the repair shop. It may take five physicians to convince a millionaire that he is not the victim of Bright's disease, but, on the other hand, if he be, perhaps twenty-five cannot cure him of his malady.

This new field of preventive medicine will have its specialists, but they will be better informed than they are to-day, and I think more numerous. The quality, rather the faculty, of observation will be cultivated with greater assiduity. The best observer will be the most skilful physician. This habit of observation will bring the physician face to face with the causes that militate to produce disease. He sees the weak point in the flange of the driving wheel, and applies the safety brake. His presence there was of the utmost importance—for he averted a disaster.

A child can pull a young tree from its earthy bed, but a giant cannot budge that tree if it be permitted to take deep root. An infant can apply a cog to wheel the instant it begins to move down a declivity, but give it a few seconds to gather momentum, and it will crash through a wall. To arrest a disease at its inception means intelligence and preparedness. Those valuable aids are summoned by the careful observer who knows how to utilize the material in his hands.

The man, whoever he be, that has eloquence and persuasion to prevent another man from eating five plates of boiled tripe in place of one is a benefactor, a conserver of energy, and an observer not without a future. For have his observations not led him to think? It was this that spurred him to action and lost a patient to the clinician of the old régime.

Knowledge is power, whether it be possessed by the specialist or some other man who may be a special specialist in a particular case. When an operation is necessary, and so formidable that an anesthetic is about to be given, the intelligent observer may here vouchsafe the information that the man nearly lost his life once before, being a bad subject for chloroform.

Gentlemen, we see in the dawn of what light the new era has so far afforded that careful observation is the sheet anchor of him who can hope to succeed in the field of preventive medicine. To observe carefully takes time, then to do a certain work properly will be not one man's portion, but ten men's.

A man is dead; his loving friendship is severed from those dear ones about him, besides the money value of his activities that could be prolonged for years. If the services of five or ten observers could have saved this man's life, it would be a boon to his family, a gain to the State, and a credit to his medical advisers. Here a benefit would accrue to all. True, it would have required the services of more observers, but since success was the object to be attained, its attainment was well worth the labor necessary to that end.

Groping in the dark, but with an effort to seek the light, the Celestial physician centuries ago attempted to inaugurate what in the near future will be accomplished. That is, anticipate disease and arrest its progress, rather than by an effort on his part to cure it. The keen appreciation of things that are transpiring will lead to a closer observation, which will furnish a storehouse of knowledge easy of access to him who possesses it, but a sealed book to the careless man, even though he be called a physician. Gentlemen, he is an accomplished clinician who knows the quality of a pulse and can tell the significance of a heart beat.

Then in the field of preventive medicine will be a great number of observers, and those observers will be physicians whose duty will be to detect a flaw in time to avert a disaster, by, if necessary, calling an assistant who will be a specialist skilled in the kind of work necessary to be done in a particular case.

Finally, it is the opinion of the writer that specialism is not overdone, but considerably underdone. This is why people, over the head of their family physician, consult a specialist, purely from delinquency on his part, who probably tarried long after he found his own efforts of little avail. This has reference to operative measures rather than medicinal ones. It is the keynote of preventive medicine that the practitioner and specialist be in close touch.

In order to do this the specialist must come down a peg or two and meet the practitioner half way, and not with an air of superiority, but on terms of equality.

Taking for granted that the specialist can do something better than the practitioner is no reason to assume that he can do everything better, and by so assuming the specialist presumes too much. This presumption the practitioner feels and resents, and from this comes the isolation of the specialist.

The era of preventive medicine that is upon us will bring more men into the field, and, as we said before, will bring them better fitted, for they will need to be, since at the present day a medical specialist and consultant has little prescience, and will say without any compunction whatever, "We must wait for developments," while he hates to wait for his fee. "Waiting for developments," sir, won't do. You must anticipate them, and correctly, and you would be able to do it if you were a careful observer —one who profited by experience.

For in the light of this twentieth century medication, old systems are being abandoned and old methods so exposed that we are ashamed of our accomplishments. Crude and barbarous they are—the conceptions of ignorant pretenders and very commonplace plodders, but we are redeemed in the fact that we saw according to our light, and acted in harmony with the meager knowledge we possessed.

Yes, gentlemen, the day of waiting to see what's going to turn up is gone forever, and even the people we meet in the sickroom to-day are not the kind of people we met there thirty years ago. The people of to-day are more keen-witted and possessed of the kind of intelligence to make the physician think, and think accurately, or they will know the reason why. Indeed, a stupid doctor has no standing in a sickroom, even in the face of an ordinary 'longshoreman or housemaid, who can tell with surprising accuracy all about the human appendix and discourse with glibness upon the germ theory.

To answer or dodge the questions, intelligent ones, these people bombard you with means that you are a live and resourceful physician. It also means that what Abraham Lincoln called the plain people will not longer be fooled with the five and ten-cent store style of medication, mostly engineered and operated by some of our brethren of a speculative turn of mind for their own pockets.

Even now, to meet the demands of the hour, the physician must come into the sickroom ready to gather round him, if necessary, associates, each skilled in his specialty. This course as an economic measure will have its value and its reward. This all-important subject has resolved itself into this—that healing the sick has grown obsolete. So much so that we physicians recognize this and try to shirk the consequences by an effort to throw the responsibility on other shoulders.

To accomplish the desired result there should be more harmonious action, more urbanity and charity. Then the practitioner and specialist will be in closer touch, making their work more congenial, their labor more efficient, and the result more certain. Then the practice of medicine will really be a science, the most efficient interpreter of which will be the most skilful physician, and the best exponent of that interpretation the most successful specialist, when the patient and his advisers have formed a partnership, a health trust, the object of which is a mutual benefit.

NECESSITY FOR SCIENTIFIC MEDICAL NOMENCLATURE.*

By A. ROSE, M.D.,

NEW YORK.

Socrates, defending himself before his judges, said: "All my life long have I been attempting to expose the weaknesses of my compatriots and to incite them to correct their errors. In future, they will probably fall to slumber, if God, out of pity, will not send another man to arouse them." And, indeed, not one man, but many great men, have appeared to enlighten the Greeks, men who have created the highest civilization and who have left to the world a rich inheritance. Aristotle, Plato, and Hippocrates, have continued to be, up to our time, the teachers of mankind.

While all civilized peoples of all times owe gratitude for the rich inheritance which the Greeks have left to them, it is especially our present time which more than any other should be reminded to keep in view the precious benefits of classical civilization. It seems as though at present money and comfort were considered the highest aims of man in this world, and science and art were valued first of all according to the material gain which they may bring.

In view of this materialistic tendency of our time it is well in place to show to our youth, to our society, that there have existed men who paid little attention to those things which are admired above all others at present, who devoted their lives to ideals and to science, who have become immortal benefactors of mankind. When we familiarize ourselves with, and indulge in the generous inheritance of classical antiquity, we imitate Juno, the wife of Jupiter, who took every year the wonderful bath which rejuvenated her. Without this rejuvenation, without this spiritual revival, men who are at the head of civilization will soon be in danger of becoming savages and bemeaning themselves.

Considered from this point of view, the knowledge of the Greek world is not only a sacred duty to all who have science at heart, but it is at the same time a sacred tribute which we owe to the great men of antiquity, and it is the first condition of our existence as men of civilization, it is the correct measure of our value as men of learning.

The names of new scientific inventions and discoveries are mostly Greek or new-formations from the Greek language, and this is natural enough, because the foundation of medical knowledge, of philosophy, and of almost all sciences was Greek, and the sciences have been transmitted to the world together with their Greek onomatology. The Romans were the first to accept from the Greek, together with medical learning, Greek terms in medicine.

The language of medicine is the result of its historical development; the chief constituent part of the linguistic treasure of natural philosophy is contained also in the confines of the classical languages. It is by this means that the sciences still bear to-day the stamp of intercommunity, simplicity, and internationality, and this fact makes it an indispensable duty for every physician and natural philosopher to acquire a knowledge of the Greek and Latin languages. A physician who has no knowledge of Greek and Latin lacks dignity. Who-

*Read at a meeting of the New York Academy of Medicine March 31, 1910.

ever admits that Greek is necessary to the physician—who more than any man has to enter deeply into every sphere of human life—must also admit that, other things being equal, the best physician (for an absolutely good physician it is not possible to find) who has no knowledge of Greek would be a great deal better if he had not disregarded that which is the crown and flower of the highest culture.

It gave me great satisfaction to read in a paper the views which Dr. John A. Wyeth has expressed in an address, "The Medical Student," delivered before the Mississippi Valley Medical Association in 1890, he said: "The decline of Greek in the classical curriculum is certainly, so far as medicine is concerned, a great mistake. . . . In Dunglison's Medical Dictionary there are approximately forty-one thousand words, of which twenty thousand are of Greek origin and twenty-one thousand are from the Latin, English, French, and Saxon. Just think of it. To the medical student without a fair knowledge of Greek, one-half of the words he uses he doesn't understand." Indeed of all that we have read on the question of Greek in our colleges this view of Dr. Wyeth, I think, is the most noteworthy.

Another mistake of our colleges is that no attention is paid to the study of the Greek language as spoken and written by the educated classes of Greece to-day. The language which we find in the classical writers was never the language really spoken by any one, not even by those who wrote it. The study of living Greek offers a broad field of linguistic, philological, literary, and practical import. The classical literature of the Greeks is but a fragment of the Greek language; without knowledge, without study of the complete language, the one spoken to-day included, much of the writings of the classics must remain unintelligible.

The Greek language of to-day is as genuine as the Acropolis is genuine. The Greeks have eliminated those foreign elements which have been introduced during Xenocraty, in the same way as they have removed the defacings of the Acropolis dating from Turkish rule. Not only the Greeks of the classical period, but also the Greeks of to-day, deserve our highest admiration and gratitude; the latter because they preserve the treasures of the ancients; the treasures of art and the purity of the language.

During the last year (1908) an important event happened in Greece which well deserves our attention. It is the appointment of a committee to prepare and to publish a historical lexicon of the Greek language, comprising all times from Homer to the present date. The members of this committee are men who are known already in the world of science. There is, first of all, Professor Hatzidakis, whose name, whose writings, are the most important of any Greek philologist of the present time, and who inaugurated the idea of the great work, the new Thesaurus of the Greek language, as it is called. Another member of this committee is Menardos, a pupil of Hatzidakis, now professor of modern Greek at the University of Oxford.

This new Thesaurus of the Greek language will be an everlasting monument to the immortality and unanimity of the Greek nation; it will demonstrate the history of the entire Thesaurus of the Greek language; it will comprise all its forms and phases, reflect the inner and outer history of the Greek nation; and it will show that the Greek nation has remained an ens, both ethnographically and linguistically, from the oldest time up to the present day.

It is true, the gigantic undertaking is yet in its initial stage; all kinds of difficulties have to be overcome, even the preparations require a great deal of time and a large sum of money, and it is well known that the Greek government, on the subsidies of which the editors have to rely, is not rich. But considering that the modern Greeks are not the only heirs of the culture which their forefathers have left to the world, that all civilized peoples of Europe and of America are heirs, that all owe a sacred duty and have a direct interest in the Thesaurus, it is to be hoped that all peoples will come to its aid, that the monument of the glorious language of three thousand years may be better understood; for such better understanding will mean a great gain foremost to the world of science.

For us physicians, too, a work of this kind means a considerable gain, because by its aid the correct scientific denomination of words of Greek origin can be definitely established. Lavoisier, in his beautiful words on the importance of correct onomatology, says: "The logic of science essentially adheres to scientific language . . . perfection in science is impossible without perfection in language . . . . however true the facts may be, however correct the ideas developed by facts, only wrong impressions will be transmitted so long as the expressions by which they are communicated are not exact."

Lucas Papaioannou, the greatest Greek anatomist of his time (he died in the year 1890), who was also a distinguished philologist, laid the foundation for the only possible scientific reform of anatomical onomatology. He studied the writings of the ancient Greek philosophers and physicians in regard to their onomatology, utilized all that was of importance for the present time, and introduced 2,700 new formations which he had constructed according to the laws of the language as only a Greek who is physician as well as philologist can master these laws. The nomenclature of Papaioannou has been introduced into Greek medical literature.

While it is necessary to acquire a knowledge of Greek, of the really spoken Greek, in order to apply Greek technical terms correctly, it is not said by any means that we foreigners are competent to coin new words from the Greek. This work we have to leave, naturally enough, to native men of learning, and, as far as medical terms are concerned, to the comparatively few of them who are at the same time physicians and thorough philologists. This fact is well illustrated in the columns of the medical journal, Ἰατρικὴ Πρόοδος, edited by John Phoustanos, who is also the editor and publisher of another great patriotic work, a complete edition of all the ancient Greek medical writers, not only those that are already obtainable in book form, but also those that have been out of print, and even those which exist only in manuscript. The texts are faithful reproductions of the originals, free from the errors that are to be found in current editions of the classical works.

In these days, of course, when books printed in the ancient languages are no longer sought for to any great extent, commercial gain can hardly be expected to result from such an enterprise; in reality it means an enormous sacrifice of labor and money. This is fully recognized by the editor; his work is purely patriotic, and that fact makes the

undertaking all the more creditable to him. Medical scholarship cannot fail to be immensely benefited by this great work, one that is sure to heighten the prestige of modern Greece in medicine.

When we compare the philological explanation of medical terms as given by this philologist and physician in his journal, with the attemps of German, American, and English committees appointed to revise medical onomatology, the members of which have never seen a Greek text-book on anatomy, we have to confess that these committees, although composed of distinguished members of the profession, cannot be taken seriously. Dr. Phoustanos has almost finished a dictionary of all the terms used by the ancient Greek physicians as well as the numerous names in our present onomatology. Of the latter those coined by foreigners who are ignorant of the Greek language present a pitiful and repulsive spectacle of barbarous distortions of Greek. This immense agglomeration of errors and barbarisms is corrected in this lexicon according to the rules of the Greek language.

One of the distinguished men of the University of Athens, Rigas Nikolaidis, professor of physiology, has in his classical book on physiology, like Papaioannou in his text-book on anatomy, constructed correct Greek terms for new conceptions which have been highly approved by the philologists and are accepted by the medical profession of Greece, as the terms of Papaioannou were accepted.

Hatzidakis, this long time and incessantly, has suggested that the scholars of Europe and America should cooperate with those of Greece. Indeed, as long as physicians and natural philosophers of the whole civilized world shall continue to name their inventions and discoveries by Greek terms, such cooperation will be the only means of doing away with difficulties and confusion. The Europeans and the Americans will then cease to take the first word they come across in the lexicon, and will have carefully selected most suitable regular denominations if they address themselves to competent Greek scholars.

One of such Greek scholars who has done noble work in revising medical terms, as to their correctness or incorrectness, and of whose explanations I have availed myself in all my writings on the subject, is Dr. Basilios Leonardos, director of the Museum of Inscriptions; as a matter of course he is, on account of his position as philologist and archæologist, looked upon as an authority. Fortunately for us, he is also a physician, a graduate in medicine of a German university. Of especial value is his book "Olympia," written in pure and elegant Greek; the style of this work contradicts all that has been said against modern Greek.

And speaking of the best men of learning, the greatest scholars of Greece, we have to mention Klon Stephanos, who is willing to aid us. His ethnographic and especially anthropologic labors I have described in my book, "Christian Greece and Living Greek." He is like Leonardos, a physician, a graduate of a German university, and, also like Leonardos, a profound philologist and linguist. While Leonardos has devoted himself to the study of inscriptions, Stephanos has made ethnography the work of his life, and both deserve the gratitude of the whole civilized world for their labors in the interest of science.

Permit me, Mr. President, after having given you these statements, these informations, and having demonstrated the necessity of a scientific onomatology, to speak as a member of the Medical Society of Athens, as a member of the committee appointed by the Athenian Medical Society, to aid in the regulation of medical onomatology. I beg to suggest that the New York Academy appoint a committee which will communicate and cooperate with our Greek brethren who are engaged in this onomatological work for the benefit of medical science.

173 Lexington Avenue.

Contribution to the Treatment of Scoliosis Automodeleur of Mencière with Pneumatic Pressure.—Louis Mencière presents a new apparatus for the treatment of scoliosis, in which the thorax is so pressed upon by pneumatic cushions during respiratory gymnastics that its normal shape is gradually regained. He makes use of passive measures consisting of *redressement forcé*, manual or instrumental, mobilization of the spine, and mechanotherapy. To this he adds modeling of the thorax during respiration as active measure. His apparatus is prepared for each individual case, a cast of the thorax being made from which a positive is made with pneumatic cushions placed over the prominent parts of the deformed thorax, and over the depressed portions spaces are provided intended to allow of increase in size as the thorax expands. When deep inspirations are made the pressure of the elastic inflated pneumatic cushions connected with a compressed air apparatus pushes in the prominent portions, while the depressed portions tend to expand into the space allowed on the opposite side. The head is fixed by a head sling suspended from the ceiling. Another exercise is given in the same position with the child exercising the arms and shoulders by pulleys. A third places him in a sitting position while the apparatus is in position and allows of exercise by lateral pulleys. During the exercises the apparatus follows the movements of respiration, the partially ankylosed costovertebral joints are limbered, and the unused portions of the lungs are inflated. All the exercises should be carefully supervised by the physician.—*Archives Provinciales de Chirurgie.*

Alterations in the Blood in Intoxications.—Consoli Nicolla and Mantano Saverio say that in the infections there is an increase in the leucocytes, especially the polynucleates. The researches up to the present day in this direction have included only the infections, and not the other intoxications. There is a large group of substances of an intoxicating nature that are formed within the body and which produce similar symptoms. The authors have made experiments on these substances, producing intoxications in animals by means of them, and then making blood counts and tests. The substances thus tested are acetone, indol, phenol cresol, and one other substance ethylic alcohol. The results found are as follows: these substances produce marked changes in the blood; only acetone has a direct action on the red blood globules producing hyperglobulia; the others diminish the hemoglobin in the blood; all cause hyperleucocytosis and polynucleosis; the lymphocytes are constantly and markedly diminished; the large mononuclears and eosinophiles are also increased; acetone causes presence of medullary cells and myelocytes. These substances have a chemiotactic action on the white globules similar to that of the infective toxins; here the polynucleated neutrophiles pass out of the medulla of the bones and get into the circulation. A phase of hyperactivity of the osseous medulla is shown by the presence of medullary cells, myelocytes, and normoblasts.—*Giornale Internazionale delle Scienze Mediche.*

Examinations for Lactose in the Urine During Pregnancy.—E. Gérard and M. Oui review the communication in which Porcher states that lactose may be found in the urine of most women in the few days or weeks before labor takes place. The authors, in order to get results confirming or against this statement, made 170 examinations of urine in 44 women at different periods of pregnancy. Three cases were thrown out as unsuitable, and of the remaining 41, the urine of whom was tested in the last few days before labor, they found lactosuria in only five, that is 12 per cent. Their results are very different from those of Porcher, lactosuria being in their observation much less frequent than that author found it to be. Out of these five cases lactose was in small amount and found but once in each case, the largest amount appearing in a woman who did not nurse her child.—*L'Echo Médicol du Nord.*

New York, April 30, 1910.

A NEW INFECTIOUS DISEASE.

IN the course of the last century immense strides were taken in our knowledge of the acute infectious diseases, and especially in the differentiation and diagnosis of the various forms of continued or remittent fevers. During the early part of the century, from the great group of "pestilential fevers" were separated various entities, chief among which were malaria, typhoid, and typhus, these being definitely distinguished upon the ground of their clinical appearance and pathological changes. The greatest step, however, in the advance of accurate knowledge of this group of diseases was made during the last decade of the nineteenth century by the work of Widal and others on the agglutinius of the blood in health and disease. It was soon found that the Widal reaction, while positive in a very considerable majority of cases presenting the clinical and pathological findings of typhoid fever, failed completely in a fairly constant minority. The discovery of the paratyphoid bacilli at first gave hope of clearing up this smaller group. Within limits this hope was realized, as many cases of paratyphoid fever were reported, and for some time a case clinically resembling typhoid fever, but failing in the Widal reaction, was often hastily accepted as an infection with one or other of the various paratyphoid bacilli. Careful attempts, however, to confirm these cases by agglutination tests and blood, urine, and stool cultures, showed that, though many of them were cases of paratyphoid, a small group still remained which could be classed in no better way than as atypical typhoid fever, showing neither agglutination reactions nor bacteriemia.

Such cases have been very puzzling to the diagnostician and the statistician, and have been entered in the records of the hospitals under the various titles of atypical typhoid fever, paratyphoid or paracolon infection, influenza, febricula, autointoxication, digestive fever, sapremia, and many other equally indefinite names, these usually followed by a conscientious interrogation point. These cases have been observed by every physician who has had to deal with typhoid fever and has attempted to confirm his clinical diagnosis by the modern more exact methods, and as a rule they have been passed over with but little thought other than that they were examples of the fallibility of laboratory diagnoses. At the Mount Sinai Hospital in New York, during the past fourteen years, 221 such cases have been seen and carefully studied by Nathan E. Brill, and the more of them the observer has studied, the more he has been impressed with the belief that he was dealing, not with an atypical typhoid fever, but with an entirely distinct infectious disease, previously undescribed. In the *American Journal of the Medical Sciences* for April, 1910, Brill presents the results of these studies, and his reasons for believing that the cases comprise an entity in themselves quite distinct from typhoid fever.

The cases studied present a striking uniformity of clinical symptoms. The incubation period of about four days is followed by an acute onset, usually with a chill and a rapid rise of temperature, which reaches its fastigium on the third day, has but very slight diurnal remissions, and ends by crisis or rapid lysis at the end of two weeks. The symptoms are severe from the onset. There is violent headache and prostration much more marked than is seen in the early stages of typhoid fever. The skin is hot and dry, and between the fifth and seventh day a profuse rash appears. This is maculopapular, of a dull red color, not infrequently petechial, and does not entirely disappear on pressure. It appears first upon the back and abdomen, but spreads rapidly to the arms, neck, legs, and at times even to the palms and soles. It comes out in a single crop and does not begin to fade until the crisis is reached, when it rapidly disappears, leaving a brown stain. The spleen is enlarged. Daily agglutination tests with the typhoid and various paratyphoid organisms have been negative in every case, and systematic blood, stool, and urine cultures have failed to show organisms of the typhoid group. Recovery is very rapid after the crises and no relapses have occurred. The only complications which have been at all frequent has been bronchitis. No intestinal hemorrhages have occurred, and no case has ended fatally.

The uniformity of this symptom complex which in many ways suggests a very mild noncontagious form of typhus fever, and the accumulation of the various points of difference between it and the clinical picture which is recognized as typical typhoid fever, present a strong argument in favor of Brill's contention that he has been dealing with a distinct clinical entity. The cases have been studied by every means open to the present day physician with the help of the best of laboratory facilities, and the investigation is lacking in no detail except that of autopsy reports, which the universally good prognosis of the disease has rendered impossible. The presentation and argument of Brill are sufficiently convincing to put every physician upon the watch for the condition, and to impress upon him the importance, in case of a fatal outcome in such a case, of a postmortem examination. The question of a name for the new disease, if such it prove to be, must remain in abeyance until more is known as to its cause and nature. If the present custom of eponymic nomenclature is followed it will probably be called Brill's disease. Brill has given us evidence that it is not typhoid fever; it now remains for him or some other observer to show, not what it is not, but what it is.

INFLUENCE OF WATER SUPPLIES UPON TYPHOID FEVER DEATH RATES.

Avowedly there are several causes which contribute to the origin and spread of typhoid fever, and some long held views must be considerably revised. Flies and human typhoid carriers have been shown to be responsible for many outbreaks of the disease, and probably these are more important factors then they are even now recognized to be. At the same time the fact must not be lost sight of that after all polluted water is the main cause of large epidemics of typhoid fever, and that the prevention of these lies in providing uncontaminated water supplies.

In the Bulletin of the Vermont State Board of Health of March 1, 1910, is an article by George M. Kober, Professor of Hygiene in Georgetown University, Washington, D. C., on the influence that water supplies exert upon typhoid fever death rates. Statistics quoted by the writer prove conclusively that the water supply plays the most important rôle in the spread of the disease. The following is a summary of the typhoid fever death rate in American cities with a population of over 30,000: The mean typhoid fever death rate from 1902 to 1906 per 100,000 of population in four cities using ground water from large wells was 18.1; in eighteen cities using impounded and conserved rivers or streams, 18.5; in eight cities using waters from the small lakes, 19.8; in seven cities using water from the Great Lakes, 32.8; in five cities using both surface and underground water, 45.7; nineteen cities using polluted river water, 61.1. The rates for cities using unpurified river water fluctuated from 33.1 in Minneapolis, to 122.1 in Allegheny and even 133.1 in Pittsburg. The effect of change in water supply on typhoid fever rates of seven American cities has been, according to Wilbur, that the combined average annual death rate from typhoid fever has fallen from 69.4 to 19.8 per 100,000; a reduction of 70.5 per cent. A convincing argument, it would seem, in favor of purifying water supplies. Kober believes that about 80 per cent. of the cases of typhoid fever are water-borne and milk-borne and about 20 per cent. may be spread through the agency of flies, personal contact, the consumption of raw oysters and shellfish raised in sewage-polluted waters, or the eating of strawberries, radishes, celery, lettuce, and other vegetables and fruits which have been contaminated with infected night soil.

In a concerted crusade, however, against typhoid fever, such a crusade as there should be in this country, the chief point of attack is polluted water. It may be asserted with the utmost confidence that four water supplies were rendered free from infection typhoid fever would soon be practically extinct. Many uninstructed members of the community are apt to imagine, now that the menace of flies, typhoid-carriers, and shellfish is widely heralded, that the danger of infected water has been exaggerated. But it has not, and the fight against impure water must go on as strenuously as ever.

The Injection Treatment of Neuralgia.

For many years the treatment of neuralgia and especially of sciatica by means of injections into or around the affected nerves has been a fairly common procedure. The number of substances used for this purpose, as morphine, creosote, carbolic acid, silver nitrate, ether, alcohol, cocaine, and many others, tell the story of the ineffectiveness or the danger of most of them. Few have given more than temporary relief, with the possible exception of alcohol, and many have done much harm by causing degenerative changes in the nerves. The work of Schleich, however, showing that by the use of large amounts of fluid containing but a trace of cocaine, local anesthesia could be produced, led several workers to try such mechanical infiltration methods in the various forms of neuritis. In the *Berliner klinische Wochenschrift* for March 7, 1910, Otto Weiner of Prague presents an interesting communication upon the injection of large amounts of ice-cold salt solution into the sciatic and other nerves. In cases of sciatica he places the patient upon his well side with the hips and knees slightly flexed so as to put the muscles slightly on a stretch. Into the painful point found between the trochanter and the tuber ischii, he inserts an 8 cm. long trocar, until he punctures the sheath of the nerve. At the moment at which this occurs the patient feels an intense lightning-like pain extending to the toes. The author insists upon the importance of obtaining this "control pain," as unless it is felt the needle is not in the nerve and the injection will be without effect. Care being taken that the needle is not moved from its position, 100 c.c. of ice-cold salt solution is slowly injected. During the injection the pain is intense, and may be associated with convulsive twitching. According to the author, however, almost immediately after the withdrawal of the needle the pain disappears, and partial or complete relief from the neuritis is obtained. The only drawback which Weiner has found to the treatment is the occurrence, three to four hours after the injection, of a high "salt fever," lasting for a few hours. This, however, he says, occurs but seldom if, instead of plain isotonic sodium chloride, a mixture containing sodium chloride 6.0, calcium chloride 0.75, water 1000, is used. The author believes that the immediate relief from pain by this method of intraneural infiltration is due to the mechanical action of the solution in stretching the nerve sheath, and breaking down the adhesions caused by the neuritic process. Of fifty-nine patients with sciatica, eight were improved and fifty-one cured after two or three injections. Of twenty-six patients with trigeminal neuralgia two were unaffected, two were improved, and twenty-two were cured. In view of the excruciating pain of sciatica and its obstinate resistance to most forms of treatment, this method of intraneural injection with saline solution seems to be worthy of a thorough trial.

The Coagulation Time of the Blood.

During the last few years the significance of the coagulation time of the blood and the importance of its accurate determination have become progressively more appreciated. It is now a routine in the more up-to-date hospitals to estimate the blood's coagulability in various classes of cases in which hemorrhage is liable to occur, especially in typhoid fever, and in cases of gall-bladder and gallstone diseases

before operation. The number of methods which have been evolved and the variety of the instruments invented for this purpose suggest that as yet no absolutely satisfactory means of estimation of this characteristic of the blood has been obtained. In the *Berliner klinische Wochenschrift* for March 21, 1910, Werner Schultz reports a new method which has in its favor simplicity and rapidity of action. The apparatus consists of four inches of capillary tube which has been blown out into twelve or more tiny bulbs. The method of working the test consists in drawing the tube full of blood and then at definite time intervals breaking off the bulbs, one at a time, and shaking them in test tubes containing normal salt solution. When this is done the uncoagulated blood is at once shaken out of the bulb, while that which has coagulated shows as a clot, which remains inside. This method, which is in reality a modification of Wright's classical procedure, has the advantage over the latter that a smaller number of tubes are handled, and the complicated system of time keeping is done away with. It has the disadvantage that a new tube, requiring no small skill in glass blowing in its manufacture, is required for each estimation.

News of the Week.

Riot Among Paris Students.—A serious disturbance took place recently in the University of Paris. Dr. Doyen attempted to deliver a series of free lectures upon topographical anatomy. The first lecture was broken up by hired ruffians or "apaches" employed by some of the medical students. It is believed that the underlying cause of the opposition to the lectures is the enmity of other members of the faculty who consider that Dr. Doyen insulted them recently in a lecture in which he lamented the lack of a Molière who could adequately caricature the foibles of the modern physician. The "apaches" not only broke up the lecture but appropriated the watches of most of the students. The course was immediately canceled by the Faculty, but will be delivered by Dr. Doyen in a private hall.

Beriberi in South Carolina.—An epidemic of what appears to be typical beriberi has broken out in a colored convict camp at Ten-Mile Hell, near Charleston, S. C. Of the 31 convicts in the camp 17 are ill and two have died. During the past five years there have been two similar epidemics in this and another nearby convict camp. There have been eight deaths in all. The camp is reported to be in a high and dry location and in excellent hygienic condition, and the food is said to be good. There is no history of the eating of rice. The convicts had been working in drainage canals.

Hookworm in Virginia.—Examination of school children in Emmerton, Va., only a few miles from Washington, has shown that 37 of the 39 pupils were harboring the hookworm.

A Case of Leprosy in New York.—A case of leprosy was reported to the New York Board of Health recently. The patient will not be quarantined.

Board of Inebriety.—The bill authorizing a Board of Inebriety in New York City, which passed the Assembly recently, has been favorably reported by the Senate Cities Committee.

Writ of Mandamus Denied to Osteopath.—The Appellate Division of the Supreme Court in Brooklyn has handed down a decision upholding the action of Justice Crane in refusing to grant a writ of peremptory mandamus to an osteopath, who is seeking to force the Board of Health and the Coroner to accept death certificates signed by himself.

The County Medical Society Loses Suit.—A jury in the New York Supreme Court has returned a verdict of $7,500 against the Medical Society of the County of New York for false arrest. The plaintiff, who sued for $100,000, was arrested in 1907, on the instigation of the County Society for practising medicine without a license. He professed to have a patent medicine which would cure glanders.

Bellevue Internes Dismissed.—The two internes who were suspended from Bellevue Hospital for complaining to the newspapers about the food have been dismissed by the Board of Trustees.

A Law Requiring Dentists to Be Physicians was passed by the last legislature of the State of Virginia. By the provisions of the new law all dentists to receive licenses must first pass the Medical Examining Board and then the Dental Board.

"The New England Medical Monthly," for 29 years edited and published by Dr. William C. Wile of Danbury, Conn., has been purchased by the Annals Publishing Company of Boston and will be combined with the *Annals of Medical Practice*. Dr. Francis D. Donoghue editor of the *Annals of Medical Practice* will continue in charge of the consolidated journals.

Robbery at Bellevue Hospital.—Six hundred dollars worth of jewelry, money, and clothing were stolen recently from a locker in Bellevue Hospital. The property taken belonged to two surgeons who were operating. The thief forced the doors of the lockers. He was not caught.

A "Siamese Twin" a Mother.—A dispatch from Prague reports that one of a pair of "Siamese twins" recently gave birth to a son in a hospital in that city. The newly made aunt expressed great surprise.

The National Bureau of Health has recently received a strong recommendation in Washington. The Anticompulsory Vaccination Society of Washington has passed a resolution opposing the passage of the bill.

Bacteriology Staged.—A play in which all of the characters represented bacteria was produced recently by the women students of the bacteriological department of the University of Wisconsin. The play, which was entitled "Germland," represented the conflict between the human race and bacteria. It was produced under the direction of Dr. M. P. Ravenel.

Belmont Hospital Opened.—The new hospital at Hempstead, L. I., which was built by Mrs. O. H. P. Belmont as a memorial to her husband, was opened April 23. It is a three-story brick building. Mrs. Belmont is the president of the hospital and Dr. Louis Nott Lanehart is secretary.

The Metropolitan Insurance Sanatorium.—The Metropolitan Life Insurance Company has purchased two farms comprising 225 acres in Somers Center, Westchester County, N. Y., for its proposed sanatorium for employees suffering from tuberculosis.

Fire Threatens Sanatorium.—Forest fires seriously threatened the Rhode Island State Sanatorium

for Tuberculosis at Wallum Lake recently. The sanatorium staff, male patients who were physically able, and many men from nearby towns, fought the fires for many hours.

Addition to Hospital.—A three-story ward building, 34x122 feet, is to be built by the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, adjoining its present buildings.

Dr. Dain L. Tasker of Los Angeles has been elected president of the California State Board of Medical Examiners.

Honors to Dr. Jacobi.—On Saturday afternoon, April 23, exercises were held at the Mount Sinai Hospital in honor of the eightieth birthday of Dr. Abraham Jacobi. A bronze bust of the guest was presented to the hospital by the medical and surgical staff, and a new library named in his honor was given by the Board of Directors. At a dinner given the same evening by the Trustees of the German Hospital announcement was made that the new children's ward which Mrs. Anna Woerishoffer has given to the hospital will be known as "The Dr. Abraham Jacobi Division for Children."

An International Hygienic Exhibition will be held in Dresden from May to October, 1911, under the directorship of K. A. Lingner and Dr. Renk, director of the Central Office for Care of the Public Health, in Dresden. The general secretary for the scientific department is Dr. Weber, member of the Imperial Board of Health of Berlin. The exhibition will be divided into five sections, under the headings of scientific, historical, popular, sports, and industry.

The American Pediatric Society will hold its twenty-second annual meeting in Washington May 3, 4, and 5, 1910, at the New Willard Hotel. The president of the society is Dr. David L. Edsall, and the secretary is Dr. Samuel S. Adams, 1 Dupont Circle, Washington.

Obituary Notes.—Dr. Augustin Hardin Goelet of New York City died suddenly of heart disease on April 26, 1910, at the age of 56 years. He was a graduate of the Bellevue Hospital Medical College in 1874. A Southerner by birth, a native of Goldboro, S. C., Dr. Goelet had spent his professional life in New York City, where he had attained prominence as a surgeon and gynecologist. Besides belonging to the New York County and State medical societies and the American Medical Association, he was a member of the American Urological Association, the American Electro-Therapeutic Association, the New York Academy of Medicine, and the New York Urological Society, and had served as gynecologist to the West Side German Dispensary.

Dr. Charles Freiberg of Bay City, Mich., dropped dead on April 1, 1910. He was a graduate of the Saginaw Valley Medical College in 1902, and was a member of the Bay County Medical Society and the Michigan State Medical Society. Until recently Dr. Freiberg was Health Officer of Bay City.

Dr. Gordon King of New Orleans was killed in an accident on March 26, 1910. He was a graduate of the Medical Department of Tulane University in 1897, and was a member of the Orleans Parish Medical Society, the Louisiana State Medical Society, and the American Medical Association. Dr. King was surgeon in charge of the ear department of the New Orleans Eye, Ear, Nose, and Throat Hospital.

Dr. Charles B. Hammond of Nashua, N. H., died at his home, April 8, 1910, aged 57 years. He was a graduate of the Harvard Medical School in 1880, and was a member of the Hillsboro County Medical Society, the New Hampshire Medical Society, and the American Medical Association.

Dr. Charles B. Mallery of Aberdeen, S. D., died at his home, April 3, 1910, aged 45 years. He was a graduate of the Albany Medical College in 1886, and was a member of the Aberdeen District Medical Society, the South Dakota State Medical Association, and the American Medical Association.

Dr. George F. Simpson of North Adams, Mass., died at his home, April 10, 1910, aged 64 years. He was a graduate of the University of Vermont in 1873, and for many years was Health Officer of North Adams.

Dr. Clarence Vary of Battle Creek, Mich., died, April 7, 1910. He was a graduate of the Jefferson Medical College in 1898, and was a member of the Calhoun County Medical Society and the Michigan State Medical Society. Dr. Vary was a former Health Officer of Battle Creek.

Dr. John B. Woodward of Ravenna, Mich., died at his home, on April 4, 1910, aged 63 years. He was a graduate of Toronto University, in 1868, and had practised in Grand Rapids and Muskegon before moving to Ravenna.

Dr. George A. Bradbury of Troy, N. Y., died at his home, April 9, 1910, aged 52 years. He was a graduate of the Albany Medical College, in 1883, and was attending physician to the Leonard Hospital in Troy. He was a member of the Rensellaer County Medical Society, the Medical Society of the State of New York, and the American Medical Association.

Dr. Maurice F. Linquist of New Haven, Conn., died at his home, April 3, 1910, aged 84 years. Dr. Linquist was a native of Sweden and a graduate of the New York Homeopathic Medical College.

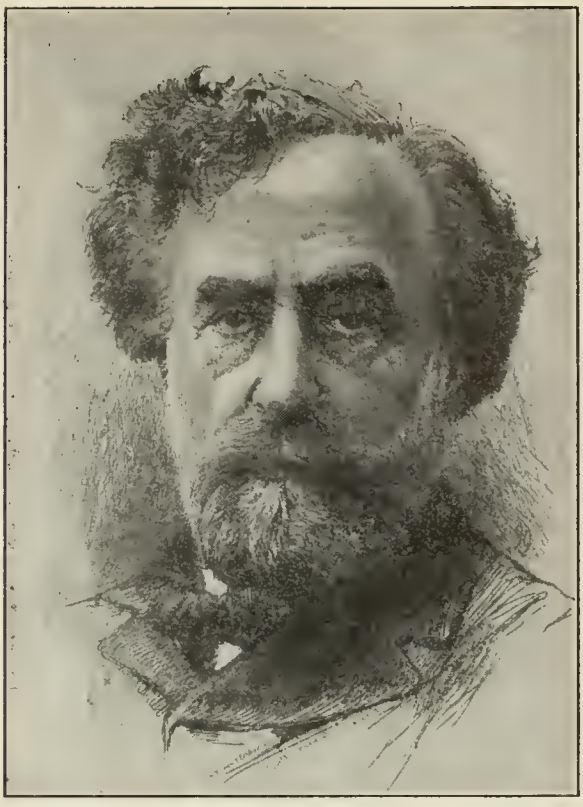
Dr. Newton Stephen Bell of Windsor, Conn., died at his home, April 11, 1910, aged 70 years. He graduated from the University of Vermont in 1864. Dr. Bell had been medical examiner and health officer of Windsor. He was a member of the Hartford County Medical Society and the Connecticut State Medical Society.

Dr. Charles P. Turner died at Philadelphia on April 13, from angina pectoris and pneumonia, at the age of 84 years. He was graduated from Jefferson Medical College in the class of 1851. He was a Fellow of the American Academy of Medicine and a musical composer of ability.

Dr. Edgar Pennypacker Brunner of Philadelphia died suddenly April 8, 1910, aged 61 years. He was a graduate of the Hahnemann Medical College of Philadelphia in 1869.

Dr. Alfred J. China of Sumter, S. C., died April 10, 1910, aged 72 years. He was a graduate of Medical College of the State of South Carolina in 1889, and was a member of the Sumter County Medical Society, and the South Carolina Medical Association. Dr. China served as a surgeon during the Civil War.

Dr. George A. Bradbury of Troy, N. Y., died at his home April 9, 1910, aged 53 years. He was a graduate of the Albany Medical College in 1883 and was a member of the Medical Association of Troy and vicinity, the Rensselaer County Medical Society, the Medical Society of the State of New York, and the American Medical Association. Dr. Bradbury was attending physician and President of the Board of Directors of the Leonard Hospital.



A LIFE FULL OF YEARS AND OF HONOR.

Dr. Abraham Jacobi, whose eightieth birthday will be celebrated next week, was born on May 6, 1830, in Hartum in Westphalia. While a student at the University of Bonn, from which he received the degree of Doctor of Medicine in 1851, he was drawn into the revolutionary activities which at that time were prevailing throughout Europe. From his political affiliations there followed certain results which enormously influenced his future career: he made the closest friendship of his life when through politics he learned to know Carl Schurz; he served two years in prison, under trial for high treason and sentence for *lèse majesté;* and he was obliged to leave Germany. Landing in New York in 1853, after a few unsuccessful months spent in Manchester, England, Dr. Jacobi opened an office in Howard street. Though but twenty-three years of age and a complete stranger, he was armed with an education superior to any obtainable in America in that day, and this, added to his force of character and his power of impressing his personality upon people, soon won for him a place in the hearts of the German inhabitants of New York. He soon became intimate with Dr. Noeggerath, at that time attaining his reputation as an obstetrician and gynecologist, and the result of their association was the production of their text-book on the diseases of children. At about the same time, at the request of Dr. Stephen Smith, then associate editor of the *New York Journal of Medicine,* he began to write a series of articles for that paper, consisting of abstracts of the current German work in diseases of children. His success in practice was immediate, especially among his countrymen, who had recently come to New York by the thousands as the result of the same revolution which had driven Dr. Jacobi from his native land.

In 1860 Dr. Jacobi's reputation as a pediatrist had increased to such an extent that he was appointed to the newly created chair of infantile pathology and therapeutics in the New York Medical College. The same year he was made attending physician to the Jews' Hospital, of whose destinies, under its earlier name as well as the present one of the Mount Sinai Hospital, he has ever since been one of the chief guides. In 1865, on the disbandment of the old school in Thirteenth street, Dr. Jacobi became clinical professor of diseases of children in the New York University, and, five years later, clinical professor of diseases of children in the College of Physicians and Surgeons of Columbia University. This position, and that of full professor he held until 1903, when his thirty-three years of service were rewarded with the position of professor emeritus. During this period, while particularly active at the Roosevelt Hospital, where he had his teaching ward, he was associated with many of the hospitals of the city, and is now on the consulting staffs of the Bellevue, Mount Sinai, German, Babies', New York Orthopedic, and Minturn hospitals, the Hackensack Hospital, and the Woman's Infirmary.

Dr. Jacobi has ever taken an interest in the social side of his profession. For forty years the German physicians of New York have held their meetings under his roof. The New York Academy of Medicine has been his especial care, and to his efforts is largely due the present efficiency of its library. Upon the foundation of the American Pediatric Society he was made its president, an office which he has also held in the New York County and State societies, the New York Pathological Society, the New York Obstetrical Society, the Academy of Medicine, the American Climatological Association, and the Association of American Physicians. Many of the medical societies of Europe have also honored him by their membership, and, indeed, he is enrolled as an active or honorary member of most of the great medical societies on both sides of the Atlantic. In 1898 the University of Michigan recognized his position among American scholars by awarding him the degree of Doctor of Laws, an example soon followed by Columbia, Yale, and Harvard.

Dr. Jacobi has always been a firm believer in the truth that to know the child one must know the man, and consequently he never confined his work strictly to the specialty of children's diseases but studied and treated young and old alike. Nevertheless, it is perhaps his achievement in pediatrics that has given him his greatest reputation. His establishment of the first teaching clinic in pediatrics in America, and his introduction into this country of the system of bedside teaching, in 1860, at the time when he held the only chair of pediatrics in any medical school on the Continent, have led to his being very justly regarded as the founder of the American school of pediatrics.

A German by birth he has become an enthusiastic American, as is shown not only by his active interest in subjects of civic, state, and national government, but especially by his refusal in 1894 of an offer to return to his native land, not to the prisoner's bench, which he left many years before, but to one of the highest honors which Germany has to bestow upon the scholar, a full professorship in the University of Berlin. In declining the offer Dr. Jacobi said that to America he owed his success in life and in America he preferred to remain.

The excellent portrait on this page is reproduced from the well-known etching drawn by the late James D. Smillie in 1899.

Correspondence.

FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE.

(From Our Regular Correspondent.)

MANILA, P. I., March 12, 1910.

THE first scientific session on protozoology and helminthology of the Far Eastern Association of Tropical Medicine met at 9 A. M., March 7, 1910, in the administration building of the new Philippine General Hospital.

There was a brief opening address by Dr. J. de Haan, who represented the Government of the Netherlands Indies, in which he emphasized the importance of such a gathering and the wish of his Government to enter into closer relations with regard to quarantine and other health measures. He felt that a mutual understanding on subjects of this kind could not help promote the interests of both countries.

The first paper read was entitled "Statistical Studies of Uncinariasis Among White Men in the Philippines," by Major W. P. Chamberlain, Medical Corps, U. S. Army, and chairman of the Board for the Study of Tropical Diseases. Major Chamberlain estimated from a study of the data furnished by the Bureau of Health, which comprised nearly 10,000 examinations, and the figures available from the Army posts, that the incidence of the disease in the Philippine Islands was probably about 15 per cent. In his opinion, the most interesting point in connection with his study of the hookworm in the Philippines was the discovery of the *Necator americanus*, which naturally led to much speculation as to how it arrived here. He stated that in the examination of the recruits at New Orleans who were destined to the Philippine Islands over 20 per cent. were found to be infected with hookworms, and from additional observation he was convinced that the Philippine Islands might have been infected with American hookworms by troops that were sent from the United States to the Philippine Islands. He questioned very seriously whether uncinariasis has the important influence on the morbidity and mortality of the residents of the Islands which is attributed to it in the southern part of the United States. He felt certain that the great majority of the cases presented no clinical symptoms of the disease, and that apparently they were not inconvenienced by it.

The next paper, entitled "Larvæ of Some Dipterous Insect Developing in the Deep Urethra and Bladder," was read, in the absence of Dr. R. Trible, by Surgeon Stitt, of the U. S. Navy. Briefly, the case was that of a sailor who was admitted to the hospital with retention of the urine. Upon passage of a catheter some obstruction was met with in the deep membraneous urethra which gradually gave way to pressure. The urine was then withdrawn without difficulty, and on examination it was found to be full of what was later identified as the larvæ of the *Musca domestica*. The bladder was irrigated with permanganate of potassium and the symptoms of vesicular irritation disappeared within a few days, as well as all of the larvæ.

The next paper, entitled "The Role of Arthropoda in Man's Life in the Tropics," was read by Mr. Charles S. Banks, of the Biological Laboratory of the Bureau of Science.

The next paper, entitled "Flies and Fleas as Factors in the Dissemination of Disease—the Effects of Petroleum as an Insecticide," by Dr. J. S. Purdy of Aucland, New Zealand, was read by title.

The next paper was entitled "Kala Azar," by Major C. Donovan, I.M.S., Madras.

The next paper, entitled "Treatment of Trypanosomiasis," by Dr. Richard P. Strong and Dr. Oscar Teague, was read by the former. If the results described in this paper prove to be permanent, its economic worth in saving the life of horses and other large animals in countries in which surra prevails can scarcely be estimated as yet. It will probably be remembered that considerable success has been had in the treatment of surra and other trypanosome infections in small animals and that failure has been almost invariable with large animals. Later Dr. Ehrlich of Germany made further investigations with the result that he produced a substance which he names arsenophenylglycin. This has been used by Drs. Strong and Teague for injection in animals. A number of horses were injected seven months ago, and since that time they have remained entirely free from trypanosomes and are apparently in good health. The principal difficulty with the remedy up to the present time is that the dose which is lethal for the trypanosomes is very close to the dose which is lethal for the animal, and the greatest care must be exercised in its use.

The next session on cholera, plague, leprosy, and immunity began at 9 A. M., March 8.

The first paper was a joint production by Dr. Francis Clark, Medical Officer of Health, Hongkong, and Dr. John M. Atkinson, Principal Civil Medical Officer, Hongkong, upon plague and the measures for its eradication and prevention. They gave an outline of the difficulties which were encountered in Hongkong in eradicating this disease, and laid particular stress upon the advantages of combating plague along the lines of its flea transmission. Dr. Clark stated that one of the most important methods for eliminating rats was by destroying their breeding places and that much had been done in Hongkong toward this end by the removal of the ceilings, especially in Chinese houses. He stated that actual experience had shown that the space between the ceilings and the under portion of the floor above furnished a most frequent breeding place, and that its removal was necessary in order to be successful. Dr. Atkinson drew special attention to the seasonal prevalence of plague, and laid special stress upon the fact that each year when the thermometer reached its high point, between 90 and 100 degrees Fahrenheit, the disease invariably disappeared. He stated that this has been observed in Hongkong for more than five years.

A spirited discussion ensued after this paper and many practical points were brought up. Dr. Brooke of Singapore stated that in spite of the fact that Singapore was but a few days' sailing distance from many plague infected ports, so far it had remained singularly free of disease, and during the first times it was imported it was eradicated with very little difficulty. He thought that the principal reason for this was the fact that the ordinary plague rat, the *Mus rattus*, which was the one that harbored the plague flea, *P. cheopsis*, was almost entirely absent in Singapore, and for that reason he believed that the ordinary means of transmission did not exist in that port, hence plague gained no foothold. He expressed the opinion that the reason which Dr. Atkinson gave, that on account of the great heat of Singapore plague did not spread there, did not apply.

Dr. Castellani of Ceylon stated that almost the same conditions prevailed with regard to communication with plague infected countries as those stated by Dr. Brooke, and that they also remained free from the disease. They attributed their freedom from the disease largely to the fact that nearly all vessels anchored in the bay and did not come alongside of wharves, and that the cargo that came to Ceylon was not of a character which would be likely to carry rats with it.

Dr. Heiser stated that he was very much interested in the paper on plague, and more particularly in that portion by Dr. Clark in which he gave the measures which, in his opinion, would be successful in eliminating this disease from Manila. On account of the fact, however, that it had been so long since there had been plague in the Philippines they had almost forgotten the measures which might have seemed desirable to put in force here It might be of interest, he said, to state that the efforts here were finally rewarded with success as soon as the theory was accepted that it would be impossible to eradicate all the rats in Manila. He stated that it would perhaps be remembered that the method finally used was to draw radiating lines from each center of infection and then to catch rats along those lines leading outward as long as infected rats could be found. When no more plague rats were encountered, the points of these radiating lines were connected by a theoretical line, and the entire available sanitary force of the Bureau of Health was stationed on this line, the force gradually moving inward to the common center, catching rats as they went Such areas were then made as rat-proof as possible by cementing ground surfaces, destroying harboring places, etc. In this way, one infected center after another was eliminated and plague soon disappeared from Manila. Since that time, at weekly intervals, it has been the custom to catch rats at the wharves and other places which were formerly infected, and at numerous other points throughout the city, and have them bacteriologically examined. In the event that a plague rat were found the same measures described above were again invoked and the area soon rendered free from infection. Since these methods had been adopted there had been no cases of human plague since 1906 and no plague among rats since 1907. Dr. Heiser stated that he also agreed with Dr. Clark as to the danger from infected rats which is to be apprehended from vessels coming alongside docks. Here it is the custom to use a special form of rat funnel, which in-

cludes a rat trap as an integral part thereof, upon all lines leading to the shore. In addition to this, he stated, the new wharves of Manila have been rat-proofed, and a good breed of rat catching cats is to be kept constantly on the docks.

The next paper, entitled "The Present Position of the Leper in View of the Resolutions passed at the International Conference on Leprosy at Bergen, 1909," by Sir Allan Perry, was read by the Secretary. Dr. Perry laid special stress upon the work of the Bergen conference and drew attention to the fact that the principles involved in the resolution had, to his personal knowledge, already been in force in the Philippine Islands during the past few years, and that the success which attended their enforcement was all that the most ardent sanitarian could desire. A general discussion followed with regard to the treatment, segregation, isolation, etc., of leprosy, and a special committee was appointed to draw up a set of resolutions which are to be acted upon at the business meeting of the Association which is to be held March 14.

The next paper, entitled "The Preservation of Vaccine Virus," was read by Dr. E. H. Ruediger of the Biological Laboratory of the Bureau of Science. He stated that considerable experimenting had been done at the Bureau of Science for the purpose of producing a vaccine which would keep at temperatures between 90 and 100 degrees Fahrenheit. Experience in the Philippine Islands has well shown that the ordinary glycerinized lymph will not remain potent for more than 5 to 7 days under such conditions. His experiments were not attended with any great success, but he had discovered that vaccine prepared with lanoline would keep for a period of approximately three weeks without losing all of its potency.

The next paper, entitled "Cholera and Other Similar Vibrios Encounters in the Philippines," was read by Dr. A. J. McLaughlin. Dr. McLaughlin drew special attention to the change which takes place in the morphology of the cholera organism and pointed out that extraneous vibrios are frequently encountered in water supplies coincidently with a cholera vibrio. He referred particularly to the recent work of Zabolosky's, and stated that his findings were practically confirmed here.

The next paper, entitled "Treatment of Asiatic Cholera," was read by Dr. A. W. Sellards, Biological Laboratory, Bureau of Science. This paper gave a series of cases of cholera that had been treated at the San Lazaro Hospital upon the theory of using large quantities of alkalies for overcoming the acid urea which had been observed in cholera cases. While no improvement in the treatment of the disease was noticed in which large quantities of alkalies were given, yet it was demonstrated that very much larger quantities of substance like sodium hydrate and other alkalies were necessary in order to produce an alkali urine than was the case in normal individuals. In the discussion which followed he also reported upon cases which were treated upon the Rogers hypertonic salt solution method, but this series of some thirty in number did not show a much improved death rate over those treated by the ordinary intravenous injections of normal salt solutions. In this same discussion Professor Aron of the Philippine Medical School stated that he was able to confirm the statement of Rogers that there was reduction in the salts of the blood of cholera patients, but in addition there was even a greater reduction in the fluid contents of the blood and for that reason the percentage of salt in such blood was not materially altered, consequently the conclusions which Rogers had reached were erroneous.

The next paper, entitled "Further Observations Upon the Specific Treatment of Cancer," by Dr. Arthur Coca of the Biological Laboratory of the Bureau of Science and Dr. Philip K. Gilman of the Philippine Medical School was read by the latter. Dr. Gilman stated that a vaccine was prepared by taking a section from a cancer tumor mass and grinding it thoroughly in ordinary salt solution and making one injection into the patient to be treated of from 20 to 30 grams of the substance. He gave a list of cases in which this had been used, which list he divided into operable and nonoperable cases. He drew special attention to the latter class in which they had made injections in 11 cases, 4 of which injections had been given 7 months ago, and as yet the patients showed no recurrence of the disease. He further stated that a few days after the injection was given the cancerous growth underwent softening, and within a few weeks entirely disappeared.

The next paper, entitled "Treatment of Plague," by Sorab K. Engineer of Bombay was read by title.

The next scientific session on surgery and obstetrics and diseases of children was held at 9 A. M., March 9.

The first paper, entitled "A Case of Congenital Absence of Both Upper Extremities," by Dr. James Norwood, Lieutenant-Colonel, I.M.S., Civil Surgeon, United Provinces, India, was read by the Secretary. This was simply the report of a case in which the upper extremities were congenitally absent. Photographs of the same were shown.

The next paper, entitled "Operations for Liver Abscess With a Demonstration of a New Operation," was read by Dr. John R. McDill, Philippine Medical School. This operation consists in resecting the ribs over the liver in a midaxillary line. This method, Dr. McDill states, gives much greater possibilities of the discovery of liver abscess than approaching the liver through the anterior abdominal wall.

The next paper, entitled "Clinical Remarks on Seventy-seven Abnormal Cases in the Obstetrical Department of the Philippine Medical School," by Drs. Fernando Calderon of the Philippine Medical School and Victor Sevilla, Philippine Medical School, was read by the former.

The next paper, entitled "Report of Cases Treated by Opsonotherapy," by Dr. Henry Fitzbutler, Biological Laboratory, Bureau of Science, gave a list of cases of skin diseases, boils and similar infections in which this form of treatment had been used. The results reported were similar to those observed in other portions of the world.

The next paper, entitled "Studies of Infant Mortality," by Dr. A. J. McLaughlin, Public Health and Marine Hospital Service, Assistant Director of Health, and Dr. Vernon L. Andrews, Biological Laboratory, Bureau of Science, was read by the latter. This paper created greater attention and interest than any that had yet been read. The work done by the authors showed that this was the first instance in which the study of infant mortality was placed upon a definite basis. The authors approached the problem by making diagnoses at autopsy, and of the ninety cases so reported it was found that only approximately twenty had been correctly diagnosed by the attending physicians. A large percentage of the cases that were clinically diagnosed as meningitis were found to be cholera. The most constant lesions found, however, were a suffused swelling of the face and neck, edema of the legs, and an enlarged heart with a dilated right side which was most characteristic in appearance and was almost identical in all cases of this kind. The authors, for the want of a better name, called this condition moist beriberi.

In the discussion which followed Dr. Musgrave stated that the cases which were diagnosed as moist beriberi presented a set of lesions that were not necessarily pathognomonic of beriberi, but were a group of lesions which had been observed in many parts of the world. He also took exception to the statement that 70 per cent. of the infants that were breast fed died while 30 per cent. of those that were artificially fed died. He stated that these figures must be fallacious because it is a well-known fact that Filipino mothers, in addition to feeding their children at the breast, were constantly known to give them solid food. Dr. Aron of the Philippine Medical School stated that the pathological conditions which had been described and called moist beriberi could be produced experimentally by overfeeding with carbohydrates and that when he read his paper he would show some dogs in which this condition had been experimentally produced.

Dr. Highet of Siam also questioned the figures on mortality of natural and artificial feeding of infants. Dr. Clark of Hongkong called attention to the fact that the high morbidity rates for children which had been found in cases that had been diagnosed as meningitis do not obtain in Hongkong. Dr. McLaughlin, one of the authors of the paper, stated that the term "moist beriberi" was not used for the purpose of claiming that the condition observed was beriberi, but that it was used for the want of a better name; it was merely intended to apply to a definite group of pathological lesions which were invariably found in these cases; and if anyone had a better name to suggest, he would be only too glad to adopt it.

Dr. Clements stated that his experience in the Philippine Islands, which was a considerable one, led him to believe that up to the age of three months infants were not artificially fed, but that whatever artificial feeding was done, was done after the period of three months had elapsed.

Dr. Heiser stated that this most interesting paper was a most valuable contribution on this subject to the Philippines, and was, he believed, in spite of all that has been said and written upon this question, the first scientific work which had been done for the purpose of securing the actual cause of death in a series of cases. With re-

gard to the statistics of natural and artificially fed infants, he said he felt that a statement should be made, that several years ago the Bureau of Health was requested to collect statistics showing whether the deaths which occurred among infants under one year of age were in cases which had been naturally or artificially fed; at that time he demurred on account of the improbability of obtaining reliable statistics of this nature by the inquiry of a statistical clerk, that it was well known to those who had experience in the Philippine Islands that almost from birth it was the custom to give rice, potatoes, and other solid food to children that were nursing, that anyone who had the least doubt with regard to the accuracy of this statement could easily satisfy himself by going through any native town and observing the children, and that in a comparatively few observations he would witness mothers engaged in this practice. Furthermore, it was characteristic of the more ignorant classes to reply to questions of this nature in the manner in which they believed an answer was desired, so that when death certificates were presented and the family was asked whether the child had been artificially fed or breast fed, that the mother would probably reply breast fed and perhaps deny other forms of feeding if she thought such an answer was desired. One year ago, at the urgent request of a number of physicians of the city, he stated that he reluctantly gave instructions to have statistics of this kind gathered, and, according to them, 70 per cent. of naturally fed children have died, which fact alone indicates that from our present knowledge of infant feeding these figures are not likely to be correct. He desired to disclaim all responsibility on behalf of the Bureau of Health for the statistics which had been used in the paper just read covering this particular point. In view of the showing made, however, he stated that an investigation would be made on this point which would be based upon actual observation of infants in their homes. The authors were to be congratulated upon the excellent manner in which they had presented this matter and the concise and clear arrangement of their statistics; they had made a valuable contribution as to the cause of infant mortality in the Philippines, and, with the data brought to light by Dr. Aron, we should soon be in position to take effective steps to reduce the mortality.

The last paper of the day was entitled "Contribution to the Physiology of Growth and Nutrition of Children in the Tropics," by Dr. Hans Aron, Professor of Physiology in the Philippine Medical School. Dr. Aron showed by experiments which he had conducted upon dogs that the overfeeding by corbohydrates produced a set of lesions which resembled very closely those described as having been found in cases that were diagnosed moist beriberi in the paper on "Infant Mortality" by Drs. McLaughlin and Andrews. In confirmation of this claim he exhibited a number of dogs in which this condition had been experimentally produced. The author was of the opinion that this matter was very closely associated with one of the more common causes of infant mortality in the Philippines, and believed that the subject was one of such importance as to warrant a further study of the same.

The fifth session of the scientific program was on fevers in the Tropics, including malaria, typhoid, etc., and was begun at 9 A. M., March 10.

The first paper, entitled "A New Bacillus Which is Apparently an Etiological Factor in Conjunctivitis Recently Observed in Singapore," was read by Dr. Gilbert E. Brooke, Delegate from the Straits Settlements, Singapore. Dr. Brooke took up the question of trachoma and contageous conjunctivitis and described an outbreak which recently occurred at Singapore in which the new bacillus was found to be invariably present. In the discussion which followed Dr. Fraser called attention to the fact that the bacillus seemed to correspond to the *Bacillus xerosis* which he had observed some years previously. Dr. R. P. Strong of Manila requested information as to how this organism differed from the *Bacillus xerosis* which they had observed at the First Reserve Hospital in Manila in 1900. In concluding his remarks, Dr. Brooke pointed out a few minor differences which existed between these two bacilli, and stated that a thorough laboratory differential test had not been made.

The next paper, on "Malarial Fever in the Puerperium," was read by Dr. John M. Atkinson, Victoria Hospital, Delegate from the Government of Hongkong. He gave a brief account of the differential diagnosis between malarial fever and septic infections during the puerperium, and laid special stress upon making a blood examination in these cases.

The next paper, entitled "The Parthenogenesis of the Female Cresent Body," was read by Captain H. M. Neeb, Medical Officer of the First Class, Delegate from Her Majesty's Government of the Netherlands Indies. This proved to be one of the most interesting papers which had been delivered at the meeting. Dr. Neeb showed drawings of the different stages of the parthenogenesis and stated that his observations had been confirmed by the School of Tropical Medicine at Hamburg as well as by other competent observers.

In the discussion which followed Dr. E. R. Stitt of the U. S. Navy stated that after many years' effort he had never been able to see anything under the microscope in the development of the malarial body which resembled parthenogenesis, and that he had many opportunities for studying such cases, especially among some sixty marines who suffered from malaria and were transferred from Panama to Washington. Within the past few months, however, a case of malaria was admitted to the Cañacao Hospital at Cavite in which he observed the phenomenon which Dr. Neeb had described and he was fully satisfied now that parthenogenesis did take place.

The next paper, entitled "Myzomyia Rosii as a Malarial Carrier," by Dr. W. T. de Vogel of Java, was read by the Secretary. This paper emphasized the importance of *Myzomyia rosii* as a malarial carrier and was confirmatory of the publications of Dr. Charles Banks, who reported the transmission of malaria by this mosquito two years ago.

The next paper, entitled "Antimalarial Prophylactic Measures and Their Results at the Naval Station, Olongapo, P. I.," by Surgeon A. W. Dunbar, U. S. Navy, was read by Surgeon E. R. Stitt. In this paper it was pointed out that the marines who went on the target range invariably contracted malaria, but that after Dr. Dunbar cleared a camping place within 100 yards of the sleeping quarters of the tall grass, the malarial fever entirely disappeared.

In the discussion which followed, Dr. Banks stated that Dr. Theobold had confirmed the view that *Myzomyia ludlowii* were absolutely identical with *Myzomyia rosii*, and for that reason the statements made by him in previous publications with regard to *M. ludlowii* also applied to *M. rosii*. He again invited attention to the fact that this mosquito did undoubtedly breed in salt water which had the composition of sea water and gave as an instance his experience at Olongapo, where he found them breeding in the ramifications of the Bay of Olongapo, which connected directly with the China Sea, and that the composition of this water upon analysis was found to correspond with the ordinary sea water. Dr. R. P. Strong stated that last year he had made a considerable number of experiments with the *Myzomyia rosii* but had absolutely failed to transmit malaria with them, nor had it been possible for him to discover zygotes in *Myzomyia rosii* which had been fed on malaria patients. Dr. Clark of Hongkong drew attention to the fact that the ordinary distance of 100 yards, which was accepted as being sufficient distance in which to clear an area of mosquitos, had proved to be insufficient at Hongkong, that is to say, that for the first year or two the plan was entirely successful, but that if there was any standing water within 400 yards in which anopheles could breed, it was likely that they would again become factors in the transmission of malaria.

The next paper, entitled "Incidence and Complications of Malaria in the Philippine Islands," was read by Dr. F. B. Bowman. This paper simply gave a statistical résumé of malarial fever in the Philippine Islands and drew attention to the fact that the Bureau of Health records showed that probably about 12,000 deaths occurred annually from this disease in the Philippine Islands. He also drew attention to the fact that at the outpatient clinic of the Philippine General Hospital it was observed that many of them complained of symptoms that were ordinarily classified as beriberi but which promptly disappeared upon the exhibition of quinine. He gave the histories of a number of cases in which arsenophenylglycin had been used but without success. Dr. Castallañi of Ceylon stated that he had observed many times similar malaria cases that presented symptoms of beriberi and that a different diagnosis between the two exclusive of the microscopic examination was sometimes most difficult.

The next paper, entitled "The Incidence and Treatment of Malaria in Infants and Children," was read by Dr. H. D. Kneedler of Manila.

The next paper, entitled "Macroscopical Method in the Typhoid Laboratory," was read by First Lieutenant J. R. Barber, U. S. Army. This was a brief résumé of a practical method which may be used in detecting typhoid organisms by physicians who do not have the facilities of a laboratory at their disposal. This plan is at present

taught in the Army Medical School for Officers at Washington.

The sixth session of the scientific program on dysenteries and beriberi was held at 9 A. M. at the Administration Building of the Philippine General Hospital.

The first paper read, entitled "The Etiology of Beriberi," by Dr. J. de Haan, Delegate from Her Majesty's Government of the Netherlands Indies. Dr. de Haan gave a brief résumé of the work which had been done with regard to the etiology of beriberi and more particularly that of Java. He presented much evidence to show that experimental beriberi produced in chickens was essentially the same as the beriberi of human beings. This finding was most important in view of the papers which were to follow.

The next paper, entitled "Etiology of Beriberi," was read by Dr. H. Frazer, Delegate from the Government of the Malay States, Kuala Lumpur. Dr. Frazer stated that Dr. Stanton and himself had undertaken a study of the etiology of beriberi in view of the report of Fletcher and others several years ago that persons who used parboiled rice did not contract beriberi, but that those who used the ordinary polished or Siam rice did contract the disease. With the view of confirming this observation and also ascertaining the exact cause thereof, they commenced further researches. His first experiments were made upon chickens which he used in groups of twelve. The first group were fed upon the ordinary white polished rice, an equal number were fed upon parboiled or unhusked rice or perhaps more clearly described as unpolished rice, also frequently known as red rice. In the first group, or that fed upon polished rice, between the sixtieth and seventieth day, eight cases of beriberi appeared. There were no cases among the adjoining group that was fed upon the unpolished rice. The experiment in these two groups was continued for a number of weeks thereafter, and the polished rice chickens gradually died off while the others remained healthy. This experiment then was repeated among many groups of chickens and the same result was obtained in each instance. The next experiment consisted in feeding the beriberi chickens with unpolished rice, whereupon they promptly recovered. The first experiment was then modified; the chickens that were sick with beriberi were fed with unpolished rice and the well chickens were placed upon polished rice with the result that the sick chickens soon became well, and after a period of sixty days or more, the chickens that were now being fed upon polished rice developed beriberi. This experiment was also repeated many times with the same result in each instance. After this it seemed most desirable to have these experiments confirmed in human beings, but considerable difficulty was experienced in obtaining conditions which were suitable for the experiment and which would not be questioned. Eventually such an opportunity presented itself; in a section of the Straits Settlements in which beriberi was heretofore unknown a railroad was to be constructed. Two hundred and fifty laborers were sent to the interior to work on this railroad, 125 were placed on unpolished rice and 125 were placed on polished rice. Every precaution was taken before these laborers were sent into this section to make a most careful examination for the purpose of determining whether they were affected with beriberi, and no one with beriberi symptoms was sent into the interior. Beginning with the sixtieth day cases of beriberi commenced to appear among the groups of laborers that were being subsisted upon polished rice, while no cases appeared among the laborers who were taking unpolished rice. This was continued for some weeks. Then the process was reversed; the unpolished rice was given to the polished rice group and *vice versa*, with the result that the beriberi soon disappeared among the laborers who had formerly been taking polished rice and after sixty days cases of beriberi commenced to appear among the heretofore healthy laborers who were now taking polished rice. The above experiments seemed to show conclusively that the ordinary polished rice was concerned in the etiology of the disease. In view of the fact that it is customary for the Straits Settlements to boil the rice before it is husked, it was thought possible that the difficulty was of bacterial origin, and a long series of experiments was made but with negative results. It was then thought that possibly some strong poison was generated in the white rice, and a large series of chemical experiments was made, but also with negative results. Next, sections were made of unpolished rice and of polished rice and a large series of these showed that the arrangements of the cells in the outer border of the unpolished rice were much closer and different from the arrangement of the cells in the polished rice; in the latter they were definitely uniform, at the center and at the periphery. Chemical experiments were then made of the polishings of the polished rice, and it was found to be very rich in pentoxide of phosphorus and that only small quantities of phosphorus pentoxide were present in the rice after it had been polished. This pericap, or polishings, was then fed to chickens which were sick with beriberi, with the result that they promptly recovered from the disease. Another series of experiments with chickens was then undertaken; chickens were fed upon polished rice and in addition with the full amount of polishings which would represent that present in the rice had it not been polished, and no beriberi developed. The amount of polishings were then gradually reduced. Beriberi began to appear when the amount of polishings given corresponded to about one-half of that which would be present in unpolished rice. During the past year unpolished rice has been substituted in all public institutions in the Straits Settlements with the result that beriberi has disappeared at all places in which this class of rice has been regularly used.

The next paper, entitled "Beriberi in Siam," was read by Dr. H. Campbell Highet, Delegate from His Imperial Majesty's Government of Siam. In this paper the author showed that beriberi appeared in Siam coincident with the steam milling of rice, which simply meant that as soon as rice was used which had been polished or which did not contain the pericap with its essential properties, that the disease made its appearance.

The next paper, entitled "Food and Metabolism in Beriberi," was read by Dr. Hans Aron, Philippine Medical School. In this paper the author independently and almost coincidently reached similar conclusions with regard to the etiology of beriberi as did Dr. Fraser in the Straits Settlements. Dr. Aron, in examining some Japanese agricultural reports, was struck with the fact that polished rice had less phosphorus than did unpolished rice, and, keeping this in mind, he carried on a series of experiments on chickens and obtained results almost identical with those of Dr. Fraser. He next had an opportunity to analyze the diet of a prisoner in the Philippines who had been placed upon bread and water as a punishment and found that it was very deficient in phosphorus. This prisoner, after being on this diet for forty-five days, showed the typical symptoms of beriberi, and when the polishings of rice were added to his diet the symptoms of the disease disappeared. Later he had an opportunity to analyze some rice which was used on a vessel carrying coal between Norfolk and Cavite, P. I. Among the Indian crew, who lived almost entirely upon rice, an outbreak of beriberi had occurred. This rice was very deficient in phosphorus. When a rice richer in phosphorus was used the disease disappeared. The author next carried on a series of experiments upon monkeys, which are now under way, and the observations made already indicate that the results will be practically the same.

In the discussion which followed, Dr. Shibayama stated that he was recently a member of a beriberi commission which had been working for the past year in Japan on the etiology of beriberi, and while they did not look for phosphorus particularly, they had made various analyses of rice and other diets which were being used by persons who were afflicted with beriberi, but found the normal amount of carbohydrates and protein to be present. He gave a history of an outbreak of beriberi in a tin mine which was apparently in no way connected with rice.

Dr. Brooke stated that a case of beriberi had recently come under his observation at Singapore, in one of the employees of the quarantine station, who had contracted beriberi while his five fellow co-workers, who lived under identically the same conditions, remained free. On account of the character of their work, the conditions could be vouched for as being the same. Dr. Highet stated that the evidence presented by Drs. Shibayama and Brooke was altogether deficient, and in his opinion did not detract from the facts advanced by Drs. Aron and Fraser in any way, nor did it introduce any factors which could not be readily explained.

Dr. Aron stated that he desired to be distinctly understood as not claiming that the lack of phosphorus was alone responsible for the symptom complex known as beriberi because he believed that the solubility of the phosphorus, the amount of time that the rice had been stored, and probably other chemical factors were concerned. Dr. Fraser stated that he desired to be distinctly understood also as not attributing the disease to lack of phosphorus alone, but that he did know that tropical beriberi could be caused by feeding persons upon an exclusive diet of polished rice. There seemed to be no question but that other conditions could cause multiple neuritis which might be termed beriberi elsewhere.

The next paper, entitled "The Bacteriology of Bacillary Dysentery in the Philippine Islands," was read by Major Eugene R. Whitmore, U. S. Army. Dr. Whitmore gave a brief history of an outbreak of bacillary dysentery which occurred in the Province of Batangas during the year. He stated that the different strains and organisms which have heretofore been described by Shiga, Flexner, and others were found.

The next paper, entitled "The Incidence of Infantile Beriberi and Its Diagnosis," was read by Dr. José Albert. The author gave a short series of cases of infantile beriberi, but the majority of his work had already been included in the paper of Drs. McLaughlin and Andrews and he therefore only gave a brief outline.

The next paper, "Ipecac in the Prevention of Liver Abscess Following Amebic Dysentery," was read by Dr. F. W. Dudley. Dr. Dudley was emphatically of the opinion that the ipecac treatment of amebic dysentery has a most important influence in reducing the number of hepatic abscesses following this infection. He also considers it to be the best form of medical treatment for amebic dysentery, as well as when hepatic abscesses are actually present.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SERUMS — ANGINA — LATENT MALARIA — HYDROCELE — PERNICIOUS ANEMIA—CANCER OF LIVER AND OTHER SPECIMENS IN PATHOLOGICAL SECTION—ITEMS—OBITUARY.

LONDON, April 8, 1910.

SERUM treatment is being tested on an extensive scale if we are to judge by the numerous preparations offered for our use. Most of these, however, seem destined to pass into the limbo where their predecessors are already forgotten. As a topic of conversation they are not very interesting, unless an ardent worker is present, for the attitude of the practitioner is generally skeptical. One remarked there are "not half a dozen" which have proved of real value, and the reply to him was that we may "speak of units, but it is much too soon to talk of dozens"—that is, in reference to their therapeutic use. Their investigation by experts is, however, watched by the general practitioner, who is always ready to try a suggestion which seems reasonable, especially on intractable cases.

The last serum—or nearly the last, for it is not easy to keep pace with their multiplication—is proposed for rheumatic diseases, acute or chronic. This is a fairly large demand on our credulity, considering that we are not agreed upon their causes nor as to the degree of their affinity. Take acute rheumatism, however, which some think is due to a microbe of some unascertained kind. How can a horse be immunized against such an uncertain cause? Assuming the disease to be an infectious fever and that it is possible to infect an animal and that in such animal it will run the same course as in man, is assuming much that ought to be proven before we conclude that the blood of the animal can be immunized against this infective fever. Skepticism is certainly natural in this case, as in many other proposals of the kind. Further, considering the proved value of the salicylates, practitioners will be in no hurry to adopt substitutes until they have abundant evidence that such substitutes are more effectual. If you demand strict evidence of the value of a serum in a single infective fever, what would you think of a proposal to use one as a sort of general immunizer against various diseases? A story of that kind has been put forward this week and found its way into some of our newspapers. It comes from the Continent, so you may possibly hear of it from your other correspondents.

Professor Osler, in his Lumleian lectures, noticed in my letter of the 25th ult., referred to cases of angina pectoris which seem to be brought on by repeatedly witnessing attacks in others, which he called "imitative." He instanced the well-known case of Senator Sumner and his physicians, as well as several others—some of his own. Among these he named one in which a "reassuring prognosis was all the treatment required to prevent any further attack in a robust patient who had been almost frightened to death" in this way. Certainly the recorded cases of emotional angina afford a wide field for the study of the effects of the mind on the body. The lecturer next considered the primary features of angina, viz., pain and sudden death. The pain is paroxysmal, intense, usually pectoral, with well-known lines of radiation; the death usually sudden, more frequent than in other disorders. The secondary features are of subsidiary interest. Pain may result from an alteration in the working of the muscle fibers in any part of the cardiovascular system, giving rise to disturbed tension of a section of the heart. As to the sudden death, which is the quickest we see, the functions of life appear to stop abruptly—a gasp or two and all is over. Some cases mentioned by Professor Osler were specially interesting as having been observed by himself. Of these one was of an old doctor who stopped at his house to write a prescription and died at his desk, pen in hand. Another fell over on his bed while talking quietly, both pulse and respiration stopping simultaneously. It seems to be vagal death, a sudden inhibition of the inspiratory center, a feeble heart-beat continuing sometimes, as we see in death from chloroform. A man of 48 was talking hopefully to Dr. Osler about going back to his work, when with a sudden cry he clasped his hands over his heart and was dead after two respirations; no pulse could be felt at the wrists, but feeble heart-sounds were heard for three minutes. Of course, such extremely sudden deaths do not often take place in the presence of a skilled observer, so the observations are the more interesting and instructive. A second mode of death described by Dr. Osler follows a series of severe attacks, the heart growing feebler and progressive asthenia, often with Cheyne-Stokes respiration, closing the scene. A third mode is seen in cardiac complications, when, after repeated attacks, cardiac insufficiency is established, even with dyspnea, and the patient sinks slowly, not so suddenly.

The latency of malarial infection is usually supposed to last for only about three years, and in a paper at the Tropical Society on March 18, Dr. Oswald Baker said he had long considered that view as correct. But he had had to abandon that belief and he related a case in which, after thirteen years of freedom, the patient had again been attacked. Clearly the plasmodium might remain latent in some circumstances for long periods.

At the same meeting Dr. A. C. Lambert gave some account of febrile cases with urticaria which had been observed of late in the Yangtse Valley. Pyrexia, rash, and prostration, followed by protracted convalescence, but mostly ending in recovery, were the symptoms, and they usually came on a few days after contact with the mud in the paddy-fields or creeks about the Yangtse. This suggested that the infective agent might be a biting fly or insect frequenting the water or some animal inhabiting the mud of the shallows. The disease has not been met with as yet except in the immediate neighborhood of the river.

Rupture of the tunica vaginalis in hydrocele is of more frequent occurrence than is usually supposed, according to the experience of Mr. Somerville Hastings, M.S., F.R.C.S., who brought the subject before the Surgical Section (Royal Society of Medicine) last month. Although it may occur as the result of traumatism, that is not often the sole cause. In fact, in most cases attributed to it additional causes must be admitted, the traumatism being of the slightest, while rupture may result from muscular action or even take place spontaneously. Further, in nearly every case in which careful examination of the tunica vaginalis has been made it has been found diseased at the point of rupture. Only the serous layer is usually involved, but occasionally the fibrous tunic is also torn. After the accident the hydrocele slowly refills, or a hematocele may follow; rarely a spontaneous cure results. The best treatment Mr. Hastings held to be radical cure of the hydrocele and the best time for operation when the greater part of the effused fluid has been absorbed.

In the Pathological Section Dr. F. H. Thiele commented on some points observed in pernicious anemia, founding his remarks on fifteen cases which he had examined. In two cases the blood was like that seen in secondary anemia. In all cases the marrow was just as had been shown by Muir to be typical. The liver, spleen, and kidney contained excessive amounts of iron. Some alimentary lesions were found in all; changes in tongue, mouth, stomach, or intestines, and pyorrhea was almost constantly noted. In some cases a streptococcus was detected. Altogether the cases go to confirm Dr. Hunter's views. Dr. Thiele detailed also two cases of "aplastic" anemia, in both of which the anemia was profound, and there was pyorrhea and a lesion of the tongue. In one there was great excess of iron in the viscera, the marrow in the long bones

was yellow, in the ribs, fatty in patches. It seemed a case of very rapid Addison's anemia.

Dr. Parks Weber showed a specimen of primary carcinoma of the liver in which there were a number of green plugs between the cells, consisting of inspissated bile. The chief part of the growth was necrotic, and the secretion of bile was considered as only what is known to occur in other glandular carcinomata.

Mr. Shattock showed a specimen of amyloid degeneration in a hepatic adenoma. This form of degeneration in a new growth has not been previously observed. The structure of the growth closely resembled the hepatic tissue which exhibited the same degeneration, the disease in both being confined to the vessels.

At the thirty-ninth annual meeting of the Chelsea Hospital for Women a deficiency in the annual receipts was announced, following a similar falling off in the previous year. Much good work is being done in the hospital and the result of advances in medical science was pleaded as the cause of extra expenses for appliances, etc., required by the medical staff. As proof of the value of these advances the report mentioned that ten years ago twenty-three operations for fibroids were performed with two deaths and last year 113 were performed without a single death.

Lady Tate, during the year, gave £1,000 to endow and name a bed.

The Midwives Act, 1902, came fully into force on Friday last. Henceforth no woman may "habitually and for gain" attend women in childbirth unless certified under the act.

The Postmaster-General has appointed a departmental committee to inquire into the cause of telegraphers' cramp and what means may be adopted for its prevention.

The death has just taken place of the Rev. T. W. Belcher, M.D., D.D., etc., the second oldest Fellow of the Royal College of Physicians of Ireland. He was educated at Trinity College, Dublin, took his M.D. and practised in Dublin, where he was physician to the Fever Hospital and became censor and librarian of the College of Physicians. He was also a regular contributor to the medical press, but in 1869 he gave up medicine and entered the church and in due time became a D.D and was rector of a parish for about twenty-five years.

Mr. Frederic Victor Milward, F.R.C.S., whose case of fatal spinal anesthesia I mentioned last week, died on the 31st ult., aged 40, after a short illness. In fact, he lay dead in his house at the time I was writing in commendation of his view that every fatality under the spinal injection plan should be recorded authoritatively.

Dr. David Davies, J.P., F.R.C.S., of Aberdare, of which he was Medical Officer of Health for forty-four years, died on the 17th ult., aged 89. He practised all through his career at Aberdare, was consulting surgeon to various collieries, and while Medical Officer of Health great advances were made in sanitary matters. He retired about three years ago. He took the M.R.C.S. in 1843 and proceeded to the Fellowship in 1862. He was a county magistrate.

Scotland's senior practitioner, Dr. John Burns of Glasgow, died on the 24th ult. in his ninety-fifth year. He qualified in the Glasgow Faculty of Physicians and Surgeons (1846), of which he later became vice-president. He retired from practice in 1905, having reached the age of 90. He traced his descent from the family of the Scottish poet.

Dr. Charles Perks, surgeon to Burton-on-Trent local hospital, and Medical Officer of Health, has also died this week. He qualified in 1864.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 14, 1910.

Diagnosis and Treatment of Peritonitis of the Upper Abdomen.—J. B. Deaver says that peritonitis of the upper abdomen may result from the perforation of a viscus or from extension through its walls. The latter form is most frequently seen as a result of the passage of infectious agents through the walls of an inflamed gall-bladder. The most frequent causes of the former variety are perforations of gastric and duodenal ulcers. Sudden pain always follows such perforations, sometimes shock and regularly a board-like rigidity of the abdominal muscles, the cardinal symptoms being pain, rigidity, and tenderness whatever may be the site of perforation. Early in the disease an acute pancreatitis may give rise to symptoms which resemble those of perforation and peritonitis. So also acute intestinal obstruction and ptomaine poisoning, both come into the question of differential diagnosis. The author gives the histories of several clinical cases which illustrate the points made and he passes in review the various operative procedures he has found of benefit. As a rule, he says, patients do not require anything in the shape of food by the mouth for three or four days after operation. He has never had any trouble in caring for them by bowel salines and expressed beef juice. He long ago abandoned the use of general peritoneal irrigation and is convinced that the same course is best for upper peritonitis. In every case a suprapubic drain should be inserted. Early diagnosis and early treatment alone offer any reasonable chances of success. If we find the gall-bladder hopelessly diseased cholecystectomy is advisable unless there is a condition of the ducts which would lead us to desire temporary or long-continued drainage. He does not believe that removal of the bladder should be done heedlessly. It is always an avenue of possible drainage if nothing else.

The Treatment of Paralytic Deformities.—R. W. Lovett makes the following varieties: A. 1. Distortion due to gravity in a wholly paralyzed and flaccid limb. 2. An adaptive shortening and lengthening of the paralyzed soft parts induced by malposition. 3. Shortening of non-paralyzed and a lengthening of paralyzed muscles. 4. Static distortion from weight-bearing in paralyzed or partly paralyzed limbs. 5. Fixed deformity of the trunk resulting from an effort to secure equilibrium. 6. Bony deformity following persistent malposition. 7. Dislocation from infantile paralysis. B. The prevention of paralytic deformity. C. Treatment of the same. 1. Mechanically. 2. By stretching of contracted tissues. 3. Shortening of lengthened tissues. 4. Influence toward normal growth by apparatus. Operative treatment includes tendon transference, arthrodesis, tenodesis and silk ligaments and finally nerve grafting. Following all these comes the matter of developmental treatment. At present the matter of tendon transference overshadows the other surgical procedures. This operation is new and easy to execute but it has been performed on many unsuitable cases, often by those who were not cognizant of supplementary mechanical and developmental measures or by those who, while cognizant of them, were not able to follow them out. Experience must come into play in the selection of proper cases. Out of thirty-seven American orthopedic surgeons thirty-one of them report that the results of their later operations were more satisfactory than those of their earlier ones.

New York Medical Journal, April 16, 1910.

A Case of Acquired Syphilis in an Hereditary Syphilitic.—O. L. Suggett has been a man of 20 years' bearing unmistakable evidences of hereditary syphilis such as the saber-blade tibiæ, enlargement of the ephiphyseal ends of the humerus, scaphoid scapulæ, serrated teeth, etc., which came under observation with a mixed sore, the size of a quarter dollar in the sulcus back of the corona glandis, the chancroidal features predominating in its make-up. The incubative period could not be determined. Bubo followed. The patient passed from under observation but two months later he reappeared with a profuse specific eruption presenting the usual polymorphism, the miliary papule predominating, interspersed sparsely with lenticular papules and macules. There was a slight fever and considerable headache. Contrary to some authorities, the acquired disease was exceedingly severe and virulent, as well as precocious, all probably due to the vulnerability of his inherited disease or rather from his dyscrasia therefrom. The author says that he has known this patient for some years and that he has not presented the appearance of being cachectic but on the contrary hardy. The history of the case given in full by the author controverts Profeta's Law as this law is interpreted by some authorities. The author is in doubt if the case falls within the category of this law, for his understanding of the latter is that the child inherits merely the immunity and not the disease, as did this patient, and furthermore, that this means an immunity *in utero*, against the mother's infection. He would welcome comment upon this point. It would seem, however, if Profeta's immunity means protection after birth, that if a child who had received only the antitoxins, born apparently healthy, enjoyed it in even a relative degree, that the child who received the virus, as evidenced by its active symptoms, and protected, therefore, by an autogenous rather than a "stock" antitoxin, should be absolutely immune. The failure of the inherited disease to confer immunity as exemplified in the case re-

ported being an unexpected condition of affairs, not having heretofore been reckoned with, may throw some light upon the supposed transmission to a third generation.

Some Points in the Differential Diagnosis of Locomotor Ataxia.—In a clinical lecture C. W. Burr says that this disease has so many manifestations that errors of diagnosis are frequently made when the patient first comes under observation. Many of these patients complain of rheumatism or muscular rheumatism. Sometimes they fall and cannot rise, telling the physician that they think the knee is out of joint but very little painful. It will be found that the pain is slight and examination shows the joint to be much disorganized. These arthropathies are always painless while arthritis and synovitis are always painful. Vomiting and gastric pain may occur, leading occasionally to abdominal exploration although the case is tabetic. Sexual desire and power, often diminished, may at the outset be increased. Rectal crises may occur suggesting neurasthenia. Optic atrophy with very little ataxia has been found. In all these cases careful observation will eventually bring out the existence, the classical triad, of tabetic symptoms, deep or superficial pain, lost knee jerk, and Argyll-Robertson pupil. Other conditions of the nervous system which require differentiation are chronic alcoholic multiple neuritis and coexistence of tabes with aortic aneurysm which has gone on so far as to produce erosion of the bodies of the vertebræ. Since syphilis is a frequent causative factor in the production of both aneurysm and tabes it is not surprising that they are both quite often found in the same patient. It is not at all common for the aneurysm to become so large as to produce vertebral erosion. Often it is only found at autopsy and not even suspected during life. When vertebral erosion does occur, however, there is set up an adhesive meningitis, and this, in addition to the direct pressure of the aneurysm, causes a compression myelitis. We may have, therefore, the clinical picture of a transverse myelitis in the legs, the local signs of tabes in the arms, and in addition to these its general symptoms. The combined picture may be so complex as to put us entirely at sea unless we remember that aneurysm may and does occur.

A Case of Disease of the Hypophysis.—This case is reported by F. W. Marlow, whose patient was a woman of thirty-six years of age. Briefly summed up it may be stated that she presented the following symptoms: amenorrhea, polyuria (six quarts in twenty-four hours); some thirst; some headache; numbness of the hands; and increase in fat; in addition to the peculiar defect in vision which led to the diagnosis of the disease. Her symptoms may be entirely accounted for by assuming an increase in the size of the hypophysis with a diminution of the functional activity of its anterior lobe. The assumption of increase in size is necessary to account for the visual symptoms which surely point to pressure on the chiasma. An *x*-ray picture is given of the head and several diagrams illustrating disturbances of the usual field.

Principles of Röntgenotherapy.—This subject is discussed by S. Tousey who describes the application of the ray to various clinical conditions. Nothing new is brought out. Concerning its use in cancer of the breast and tuberculosis the author says that it sometimes happens after the first mild application to a cancer of the breast that a toxemia occurs. A patient of the author had a cancer of the breast which she concealed as long as possible and she also concealed the recurrence of cancer in the operation cicatrix and also in the other breast until removal was absolutely contraindicated. The first mild application over this large breast made up of cells especially susceptible to the *x*-ray, caused an amount of internal disintegration and absorption which produced a rise of temperature and other symptoms of toxemia. These symptoms did not recur after subsequent treatments. It has been very distinctly proved that *x*-ray treatment does not cause metastases and internal involvement but on the contrary has the strongest tendency to prevent them, and if this treatment is adopted before the disease has become disseminated some patients may be entirely cured. Tuberculosis of the bones, joints, and lymphatic glands is often curable by the *x*-ray. A tuberculous gland treated in this way undergoes a change into a small fibrous nodule, and the lymphatic channels connected with it are converted into fibrous cords. The tendency is not only to cure the local disease but also to prevent systemic infection. Tuberculosis of the larynx was cured or at all events healed in one of the author's cases, but one lung was already badly affected and the patient died of pulmonary tuberculosis. The *x*-ray alone will not cure the latter disease, but it is a valuable adjunct to outdoor life, climate, hygiene, and the application of high frequency currents. In tuberculosis as well as in other diseases the benefit from the *x*-ray is not due to a direct effect upon microorganisms but to an effect upon the tissue cells.

Journal of the American Medical Association, April 16, 1910.

Ocular Palsies in Tabes.—W. C. Posey remarks on the importance of eye examination in tabes and particularly notices the palsies of eye muscles so frequently observed. These, while resembling the palsies from other causes, possess certain characteristics peculiar to themselves. The first is their transient tendency in the early stages of the disease, a character also marked, though less prominently, in the later stages. A history of diplopia can often be elicited from patients who are loth to believe that it has any connection with the later symptoms. In addition to the transient tendency there is the marked disposition to recurrence. The palsy may last only a few hours or even persist for years and the return of the muscle to its normal action even after long periods should be recognized as a possibility in tabetics and tend to discourage operation in such cases. Their tendency to occur early in the disease has been noted by most observers though they may occur at any stage. According to statistics given by Uhthoff and others, palsy of the eye muscles in tabes in adults is more common than optic atrophy, which is seen, according to Uhthoff's figures, in from 18 to 20 per cent. of all cases. They are not so common in the initial stages, however, as the Argyll-Robertson pupil or as lancinating pains or loss of reflexes. Rarely, muscles other than ocular may be palsied at the same time, such as those of the palate and vocal cords. It is worth remembering here that that form of tabes beginning with optic atrophy is often for a long time combined with loss in power of the roots of the thoracic nerve when all other symptoms are absent. Posey finds from his experience that inequalities in the size of the pupil and disturbances of its reaction are found in the early stages of cerebral syphilis, often associated with optic neuritis, while palsies of the extraocular muscles as a rule belong to the later stages. Contrary to the rule in tabes, they develop more gradually and persist longer instead of showing a tendency to early disappearance and frequent recurrence. Conjugate deviations and ophthalmoplegia externa are caused almost exclusively by syphilis. Uhthoff has suggested that a nontabetic ophthalmoplegia can readily be differentiated from one of true tabes by the presence of an unaffected pupil. We must remember, however, that a true syphilitic ocular palsy may coexist with tabes. In fact, tabes often cannot be distinguished clinically from nervous syphilis. Posey thinks that there is good evidence that tabes is not directly the result of syphilitic virus, but results from parasyphilis from some toxic substance produced in the body. The pathogenesis of ocular palsies in tabes is still in doubt but the common view is probably that they are either pathological occurrences superimposed on the general disease or that they are part of the latter, *i. e.* that they are syphilitic ocular palsies occurring in tabes or they are simply a manifestation of the general motor disturbances observed in that disease. Fraenkel's view is that in their earlier stages they are simply due to loss of tonus which is mediated through the disease of the sensory neuron, while later on, when, owing to the long duration or severity of the process in the sensory neuron, the motor neuron has undergone secondary changes, palsies are more lasting, more extensive, and their immediate cause is found to exist anatomically in degeneration of the nucleus, nerve trunk, or muscle.

The Eye in Idiocy.—L. Pierce Clark and M. Cohen have studied the eyes of idiots to observe the fundal changes and find in fully three-fourths of all cases out of a total of 129, varying degrees of retrobulbar neuritis of a degenerative character. The eye defects, however, do not seem usually to extend beyond a functional incompetence of vision and this may be explained perhaps by the defective central innervation. External changes in the organ of vision were found in but few. The pupillary reflexes to light accommodation, etc., were present in all but sluggish in the idiots. The acuity of vision, the field of vision and the refractive errors could not be determined. In 29 feeble-minded individuals but 9 exhibited normal fundus and but 15 in 24 imbeciles. But 2 out of 53 idiots showed normal fundus. The appearances found most frequently in all three classes were pallor of the temporal half and edema of the nasal half of the disc, and incipient atrophy as shown by generalized pallor. One imbecile and three idiots showed well-marked atrophy of the disc. No specific cause is offered to account for these findings but their constancy in the majority of cases is emphasized.

Trichinella Spiralis.—E. M. Packard reports a case of infection by this parasite in which the trichinella was found in the circulating blood of an Italian woman who had been suffering for three weeks with headache, pains over the whole body, anorexia, occasional diarrhea, and weakness. She was markedly prostrated and had had several attacks of epistaxis. Until recently no proof had been furnished of the passage of this organism in man from the intestines to the muscles by way of the chyle and blood streams, and Packard offers the case as evidence of the fact.

Difficult Surgical Problems.—J. A. Wyeth gives details of a number of difficult operations illustrating surgical principles, including the transplantation of the proximal end of the ulna to the distal end of the radius in an ununited Colles' fracture; fracture of the radius with faulty union causing complete loss of pronation and supination treated by refracture of bone with divulsion of contracted muscles and resulting in reunion and restoration of function; the reproduction of the carpal end of the radius after destruction by gunshot wound; the treatment of fracture of the femur in a new-born infant; also his views in regard to certain special surgical features. Among these are his method of treatment of caries of the lumbar spine by continuous extension, the treatment of vascular tumors of the neck by injection of water at a high temperature, experimental studies on animals, and operations on human beings of permanent arterial occlusions after deligation by the use of broad animal ligatures, ligation of the external carotid artery, and his method of bloodless amputation of shoulder and hip joints. blood streams, and Packard offers the case as evidence of the technique. The article is illustrated.

Intraspinal Tumors.—C. A. Elsberg reports a case of extramedullary tumor of the cervical region which was operated on by removal of the spines and laminæ of several lower cervical and the first dorsal vertebræ. When the dura was incised the tumor extruded, but owing to the patient's condition further immediate operation was deferred and the wound closed. A week later the wound was reopened and it was found that a tumor, measuring 5 cm. in length and 3.5 cm. in breadth, had been almost entirely extruded from its bed under the pia mater so that it lay outside the cord substance and could be removed with great ease and with the minimum of danger to the cord. A fuller report of the case will be published by him and Dr. Fraenkel at a later date. This preliminary report is given on account of the suggestion it offers for the treatment of similar cases. He believes that operation for tumor of the spinal cord should be made always in two stages and that the first stage should end, not with the laminectomy, but with the small incision in the dura and also in the pia if the growth is subpial. If the tumor is subpial or intramedullary the dura may be closed at the end of the first stage. A fuller discussion of the advantages and disadvantages of the method is promised in the future publication.

The Lancet, April 9, 1910.

Effects of a Serum Upon a Carcinoma Occurring in Mice.—C. Walker gives a description of experiments performed by him and several microscopic pictures of his findings. It appears that while normal rat serum under the conditions of his work leaves a large number of cells of the particular carcinoma employed in mice in an apparently healthy condition at the end of forty-eight hours, the serum of rats treated with a mouse's testis produces a reduction of the tumor cells, although it apparently allows at the same time other cells to proliferate. A large number of these small cells which take the place of the cancer cells are apparently leucocytes. A comparison between them and the spleen and bone marrow of the mouse makes this obvious without going into particular details. It is, of course, possible that some of the cells may not be normal leucocytes or derived from leucocytes. The conditions being obviously abnormal, it is only to be expected that if they are all of them leucocytes, as the author is inclined to think, the appearance in many cases must vary considerably from the normal varieties of leucocytes. A large number of them are typical, being mainly lymphocytes and polymorphonuclear leucocytes. Some, too, contain granules. There is also apparently an increase of connective tissue cells. The general results seem to show that what happens upon the treatment of a mouse suffering from cancer with the testis serum is rather upon the stimulation of the leucocytes to multiply and replace the tumor cells than a direct destructive influence on the part of the serum upon the cancer cells themselves.

Experimental Diminution of Resistance to Mouse Cancer.—A. Leitch says that injections of a fluid prepared from an adenocarcinoma, instead of increasing the resistance to test inoculations, had a marked effect to the contrary. In ten days' time of 27 treated mice that remained alive 18 showed tumors. A week later 21 out of the 27, or 78 per cent., had growing cancers. The controls gave 9 tumors in 27 mice, or 33 per cent. There is a striking disparity in the two sets. But this disparity is all the more marked when we take into account the size of the tumors produced in both cases. By carefully mapping out the contours of the tumors on graph paper it was found that the average area covered by the growths in the treated set was approximately 110 square millimeters, as compared with an area of 39 square millimeters in the case of the controls and the average mass was much larger. From these experiments it is evident that the injection of cancer cells which are physically disintegrated without being probably chemically altered had markedly affected the resistance toward living tumor cells. So far from conferring anything like immunity, it undoubtedly exalted the susceptibility.

Notes on the Use of Adrenalin Chloride in the Treatment of Plague.—E. N. Thornton has had experience in 50 cases, of which 15 died. For adults 30 minims of a 1/1000 solution were at first usually given by the mouth, with 10 minims of tincture of strophanthus every four hours for the first three days and three times daily for the following fourteen days. Later, if the patient was very ill, the adrenalin was given hypodermically or intravenously in somewhat smaller dose. The mixture for oral administration was made up freshly as required. In the worst bubonic cases it was customary to commence with an injection of 20 minims of the adrenalin chloride in the neighborhood of the buboes, especially where the latter were unusually painful or where much extravasation was occurring into the surrounding tissues. In general the hospital mortality from the lesion (excluding septicemic cases) in those cases not treated with adrenalin has been 37.4 per cent., as compared with a mortality of 26 per cent. only among those treated with adrenalin. This lower mortality does not appear to have been due to the fact that the adrenalin patients had the disease in an unusually mild form, for if anything they appeared to be somewhat worse than were the majority of cases under treatment, especially those toward the middle and end of the series. Autopsy showed in nearly all the cases in which the remedy has been employed and failed a marked diminution in the usual congestion of the organs, no hemorrhages or petechiæ, less effusion into the pleuræ and pericardium, less enlargement of the liver and spleen, and very little enlargement or alteration in the appearance of the suprarenal glands.

Arthritis Deformans.—R. L. Jones says that under this heading we have to distinguish three varieties of cases: (1) Rheumatoid arthritis or atrophic arthritis, (2) osteoarthritis or hypertrophic arthritis, and (3) infective arthritis. He passes in review the pathological changes in each of these forms and passes on to consider the nature of the new bony formations which appear sometimes in these cases. Sometimes, also, complete cases appear in which skiagraphy will show no new bone formations. These are not to be regarded as essential to the disease, but are rather secondary features. The author is not disposed to agree with those who believe that their presence is evidence of the transition of a condition of rheumatoid arthritis into one of osteoarthritis, but says that the morbid process in the former condition is one of rarefaction and softening. Consequently it follows that by reason of this pathological change these structures are peculiarly susceptible to stresses and strains. In other words, the ends of the bones tend to undergo plastic adaptations in their shape as the result of the retraction of the skin and pericapsular tissues aided by the pull of the related muscles. The testimony of skiagrams tends, the author says, to strengthen his views on this point. Hoffa has said that these proliferations are in proportion to the amount of atrophy that has occurred and he would regard them as reparative in nature. Now, were the proliferative changes in rheumatoid arthritis of the same nature as those in osteoarthritis, one would expect that their size would be in relationship to the length of the disease. On the contrary, it would appear from the experience of various authorities that, notwithstanding the existence of the disease for prolonged periods, bony outgrowths were

absent, whereas in much shorter cases they were present.

British Medical Journal, April 9, 1910.

Nourishment in Acute Diseases.—F. G. Haworth notes that it is quite a common experience to find a patient out of bed for the first time not more than a quarter of an hour, quite depressed and sometimes in tears because of the unexpected weakness, and this after a great deal more nutriment has been taken than often happens when in normal health. Physiologically we do not draw our strength from our food. Surely the whole of that goes to make good the loss of tissue which is always going on in the economy. Dead tissue is constantly being thrown off and new cells are born and go to make good this loss. Hence comes the popular saying that "we have a new body every seven years." Of what avail, then, is all the nutriment we take? None, says the author, except to build up the burnt-out tissues the result of an attack of, say, pneumonia. But with a temperature of 104°, a furred, foul tongue, and pronounced anorexia, loading up of the bowels with accumulated waste, and innumerable organisms of infinite variety and infection, it is better to wait for convalescence, with its rested and recuperated stomach, cleared out bowel, and a mind free from the terrors of delirium. We should watch the pulse and improve this by increasing the blood pressure by means of copious draughts of hot water or saline injections by the rectum, or by both, and we shall not need to fear collapse or heart failure.

Pigmentation of the Buccal Mucosa in Pernicious Anemia.—T. G. Moorhead records the history of a case of this disease in a man of 28 years of age. He presented the usual symptoms of the malady, but the most striking feature was the pigmentation of the lips and mucous membrane of the inner aspects of the cheeks. The lower lip on its inner aspect was of a bluish, inky color, and this discoloration was prolonged on the inner aspect of the mouth on both sides, principally on the line of junction with the teeth in the form of scattered inky patches. Similar patches less deep in color were also present on the inner aspect of the right cheek below the level of the teeth. Under arsenic the case was doing well when reported. The pigmentation was lessening, doubtless owing to the fact that the contrast between it and the remaining mucous membrane is not so sharp, owing to the gradual return of the latter to its normal color. The author has been able to find on record only four cases with this special location of the pigmentation.

Berliner klinische Wochenschrift, March 28, 1910.

Transplantation of the Kidneys.—Ernst Unger reviews briefly Carrel's results with kidney transplantation and reports two attempts of his own to transplant the organs between monkeys and human beings. The first experiment followed the technique of Carrel, except that the donor was a still-born baby and the receiver a medium-sized baboon. Through technical errors the animal died. The second experiment was in transplantation from a monkey to a human being. The patient was a 21-year-old girl with advanced nephritis and very marked edema. The prognosis being hopeless, the operation was undertaken. The donor was a *Macaccus nemestrinus*. From this ape both kidneys were removed *en masse* in the usual manner, with the adjoining portions of the aorta, vena cava, ureters, and bladder. An incision was then made in Scarpa's triangle in the patient, and the fragments of aorta and vena cava were implanted into the femoral artery and vein. The skin was undermined in the thigh and the ureters and fragment of bladder were passed under this, the latter being sutured into an opening made through the skin in the anterior internal aspect of the thigh. The patient, who was *in extremis* before the operation, died thirty-two hours after it. The circulation had remained good in the implanted kidneys. At autopsy these kidneys showed no signs of degeneration. Whether they had functionated or not could not be said definitely, as edema fluid was discharging from the opening in the skin.

Deutsche medizinische Wochenschrift, March 17, 1910.

Operations with the Electric Spark and Diathermia.—Vincenz Czerny has investigated the effect of fulguration, high-frequency currents, and Nagelschmidt's diathermia upon carcinomata in various locations. From these experiments and observations the author concludes that in these therapeutic procedures we have means of destroying local cancers, but, at least in cases previously operated upon, they do not prevent recurrence any more certainly than any other previously used methods. However, we are rarely able to use the method in the early stage of cancer, when it might be of some value in treatment if the patients would consent to the bloodless destruction of the tissue as readily as to the bloody operations. He considers it important that the methods be given further trial in order to prove, as may be the case, that by electrical treatment the deep lying cancer germ may be so debilitated by the currents that the natural curative power of the body, helped possibly by artificial aids, may destroy it and thus bring about a cure. Further experience will teach the true value of the various methods and show us how far we should go with them in order to obtain the best results. The experience which the author has had with fulguration leads him to offer the warning that only such physicians should make use of diathermia, the electrocaustic, and the spark as have operative experience, technical skill, and physical knowledge of the high-frequency currents, or else can command a technician or physicist to be on hand with advice and help. These very energetic currents may easily do great damage.

A Simplification of the Neisser's Stain for Diphtheria Bacilli.—Paul Sommerfeld has proposed a modification of the Neisser stain which is simpler and requires fewer staining reagents than the original. The stain is based upon the fact that the granules, when once stained, retain their color better than the bodies of the bacteria under decolorizing agents. The method is as follows: The smear, dried and fixed in the usual manner, is overstained with methylene blue (Loëffler's, alcoholic, or watery), washed off with water, or dried with filter paper, and then placed in equal parts of 40 per cent. formalin and alcohol until the color has disappeared. It is then washed with water and dried. The granules stain a dark blue, the bacterial bodies a light blue. Counter staining is quite unnecessary, but can be done if desired with vesuvin, chrysoidin, or eosin.

The Wassermann Reaction and Narcosis.—Georg Wolfsohn has studied the Wassermann reaction in fifty operative cases immediately after the operation, under morphine-scopolamine-ether narcosis, and again several days later. He found that in 22 per cent. of the cases a positive reaction was obtained during the narcosis, which disappeared in a few days. One must, therefore, be careful not to make a positive diagnosis of syphilis from the results of a test made while the patient is under the effects of a narcosis. This anomaly of the reaction probably has some relation to the effects of narcotics, which are supposed to act by dissolving the lipoids out of the brain and the association of lipoids with the Wassermann reaction.

Hecht's Modification of the Wassermann Reaction.—König discusses the Wassermann reaction and especially its modification made by Hecht. He says that the fact that in a certain proportion of the cases of untreated syphilis the Wassermann reaction is negative and the consideration that possibly these failures are dependent upon the complicacy of the method is the reason for changing and simplifying the original method. A modification of a test is indicated if it fulfills the following three requirements: (1) It must be based upon a scientific foundation; (2) it must be simpler and more delicate than the original method, and (3) it must never give fallacious results. All of these requirements are fulfilled by the Hecht modification, which depends upon the fact that normally human serum is capable of dissolving ten times its volume of a 2 per cent. solution of sheep's blood. For Hecht's test one needs only active serum, 2 per cent. sheep's blood, and antigen. The modification gives very good results and never fails if one uses fresh serum only and works with a dose of antigen which is not bound by twice the amount of normal serum.

Anatomy of the Male Urethra.—De Meritt says that surgically it is more convenient to recognize six divisions of the urethra than the three usually given by anatomists. These divisions with their logical names are : (1) the glandular, (2) the cavernous, (3) the bulbar, (4) the pretrigonal, (5) the trigonal, and (6) the prostatic. The first three divisions are contained within the corpus spongiosum.—*Journal of the Medical Society of New Jersey.*

Book Reviews.

The Practice of Medicine. A Text-Book for Practitioners and Students, with Special Reference to Diagnosis and Treatment. By James Tyson, M.D., Professor of Medicine in the University of Pennsylvania and Physician to the Hospital of the University; Physician to the Pennsylvania Hospital; President of the College of Physicians of Philadelphia; Member of the Association of American Physicians, etc. Fifth edition, revised and enlarged. With five plates and 245 other illustrations. Philadelphia: P. Blakiston's Sons & Co., 1909.

It is a pleasure to welcome the fifth edition of this well known text-book on the practice of medicine. It has always been one of the best books of its type, especially as it is largely written from the author's own vast clinical experience. Despite the difficulties which must be encountered in attempting to keep a volume of this magnitude up to current practice, it would seem to the reviewer that the aim had been admirably accomplished. The new sections on the use of tuberculin, on the Cammidge and the Wassermann reactions, and on other clinical laboratory methods are sufficient to give the student an idea of the main points of the procedures, while not attempting to supplant the standard text-books on laboratory diagnosis. Evidences of the thorough revision of the section on tetany, with full recognition of the important work of MacCallum on this problem, show that the author has succeeded in covering the latest literature of this complicated and still rather obscure subject. An excellent discussion of the treatment of exophthalmic goiter, especially the anti-serum method proposed by Rogers and Beebe, also shows how fully the work has been revised. Many other new points have been inserted which need not be mentioned here, but it is sufficient to say that the volume offers a most valuable guide to the student of medicine. The only possible criticism is directed largely at the proof-reading, a number of misprints, especially in the names of authors, occurring throughout the text.

A Manual of Medical Jurisprudence. for the Use of Students at Law and of Medicine. By Marshall D. Ewell, M.D., LL.D., late President and Dean of the Kent College of Law, Chicago; Lecturer on Medical Jurisprudence at the University of Michigan, etc., etc. Second Edition. Boston: Little, Brown & Co., 1909.

Some text-books on medical purisprudence should be in the possession of every physician and every lawyer. Usually it is best to select a work of considerable breadth and scope, for reference; but for the student and as a hand volume, Dr. Ewell's book may be recommended. The first edition appeared in 1887, and the present edition shows relatively few changes, considering the time which has elapsed and the advance which has been made since then in medical science. The author states, however, in his preface that this advance has been taken into consideration in his examination of the text; and it will be noticed that references have been added to each chapter for the convenience of further study of any particular topic. These references are both to text-books and to cases cited from medicolegal practice in the courts. Too little attention is still paid to this practical and important branch in the medical college, and perhaps also in the law school. At any rate, both physicians and attorneys seldom exhibit a good knowledge of the subject. The usual topics are considered in the book: Evidence, experts, compensation, signs, modes and causes of death, personal identity, abortion, infanticide, rape, legitimacy, life insurance, feigned diseases, malpractice, toxicology, insanity, etc. Of necessity all subjects are treated briefly. The chapter on insanity, from a medical point of view, is not well brought up to date. The important classification of Kraepelin, for example, now universally used, is omitted.

The Campaign Against Microbes. By Etienne Burnet, M.D., of the Pasteur Institute, Head of the Vaccination Service of the City of Paris. Translated from the French by E. E. Austen, F.Z.S. New York: William Wood & Company, 1909.

The first chapter in this work deals with the subject of cancer. A full description of the experimental work being done is offered the reader, together with the hypothesis at present popular. The *pro* and *con* of the various theories are considered and we are left with the conclusion that it is due to some unknown parasite. The second chapter takes up the subject of tuberculosis, and although we know much about this disease, the author points out how little has been accomplished aside from hygiene in its therapeutics. The results of Von Behring's bovo-vaccine are considered as failure pure and simple. The following pages present the work done on sleeping sickness, tetanus, and diphtheria, where scientific investigation has helped us to offer relief and cure. The chapter on intestinal microbes is most interesting and deals with the work of Metchnikoff and his new ideas of limiting the growth of the harmful ones by substituting a more beneficent variety. Vaccinia and variola are the subjects with which the work ends.

The author has given a fair minded exposition of modern scientific investigation, and makes no attempt to force his own conclusions on the reader, but allows him to form his own unbiased opinions. The descriptions are clear, the language as untechnical as it is possible to use on such a subject. It is a book of value to physician and patient, provided he takes a normal and not morbid interest in such knowledge.

The Morphia Habit and Its Voluntary Renunciation. A Personal Relation of a Suppression After Twenty-five Years' Addiction. With Notes and Additional Cases. By Oscar Jennings, M.D. (Paris), Fellow of the Royal Society of Medicine. New York: William Wood & Company, 1909.

This book of nearly 500 pages sounds an optimistic note in the treatment of drug addiction. The author deplores the pessimism with which the profession treats of this subject and explains the reasons of so many failures. He disclaims the necessity of coercion or restraint and lays great stress on the reeducation of self-control. The aim is not only to suppress the use of opium, but also to suppress the desire. It must not be understood that the writer decries the medicinal treatment which must accompany the psychic. He fully realizes the necessity of ameliorating the misery of abstinence and uses sedatives at appropriate times. In fact, he lauds the use of heart tonics, of agents which neutralize acidity, and the Turkish bath. The environment of the patient, the education of his confidence in his adviser and in himself, the attention to detail are all emphasized as important. The value and drawbacks of sanatorium, hypnotic, and suggestive treatment are duly considered. The latter part of the book deals *in extenso* with the histories of various habitués, with those who also have added other addictions, such as tobacco, cocaine, and alcohol; with cases complicated with heart disease, and rheumatism, etc. His results of 90 per cent. successes should stimulate the profession to emulate his example and imitate his methods.

A Text-Book of Medical Treatment (Alphabetically Arranged). By William Calwell, A.M., M.D., Physician, Royal Victoria Hospital, Belfast; University Clinical Lecturer on Medicine, Queen's University, Belfast; Consulting Physician, Ulster Hospital for Women and Children, the County Antrim Infirmary, the Throne Consumptive Hospital, Belfast, and the Old Charitable Institute, Belfast; Lord Chancellor's Medical Visitor in Lunacy, Belfast District; ex-President, Ulster Medical Society, etc. London: Edward Arnold; New York: Longmans, Green & Company, 1910.

This work is the outcome of twenty years' teaching, and as such is unusually complete and satisfactory. The subjects are arranged alphabetically, thus making them readily accessible to the hurried reader. The diseases usually coming under the management of the internist compose most of the text, although many other subjects are included. Under appendicitis we notice the recommendation that opium be employed for the control of pain, and the author seems unduly pessimistic about the results following early operation in fulminating cases. Throughout the book the author shows his knowledge of contemporary practice and has evidently kept pace with the literature of his subjects. He gives the best and accepted treatments, and is evidently safe and sane and without dangerous enthusiasms. His attitude toward specific treatment of tuberculosis shows conservatism, hope for a development of the same and yet a true dependence upon fresh air and food as the best therapy that is at our disposal up to date. He gives the details of methods at present under trial and reserves judgment. Such methods as are being generally accepted, like Flexner's serum in spinal meningitis, he recommends.

The broad-minded clinician appears throughout the book, drugs are used, and the limitations and advantages thoroughly recognized, but in addition much stress is laid on dietetics, hydrotherapy, hygiene, rest and exercise, climate, *x*-rays, electricity, and such physical measures as are gradually supplanting the more mystic prescription for drugs.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held March 10, 1910.

DR. ELI LONG IN THE CHAIR.

A Case of Salaam Convulsions.—Dr. SIGMUND ARTHUR AGATSON presented a boy, four years old. His father and mother were first cousins, with normal mental and physical conditions. The child was born at the seventh month. During the first six months of life he gave no trouble; then he began to cry frequently unless taken up and carried. During the first year he never had any convulsions. His present trouble began at the age of fourteen months when the mother noticed that upon awakening the child would bow the head and bend the trunk; these attacks recurred from eight to ten times a day, and were most marked after sleep. They came on without any premonition. There was a sudden bowing of the head, the chin touching the sternum. Simultaneous with this there was an inclination of the trunk to about an angle of 60 degrees when in the sitting posture. The right arm, partially flexed at the elbow, was brought forward in slight abduction until it reached the level of the shoulder, the palm with fingers extended pointing downward and inward. During the spasms there appeared to be a momentary loss of consciousness. Between the spasms the child appeared to be contented, at times smiling and clasping his hands in apparent joy. Each attack consisted of twenty or thirty spasms, lasting about twenty seconds, occurring at intervals of fifteen to thirty seconds. The child had been under observation for eighteen months and there was no perceptible improvement in his condition.

A Case of Tetany in a Child Eleven Months Old.—Dr. WILLIAM SHANNON presented a baby, eleven months old, who had been apparently well up to three weeks ago. When Dr. Shannon saw the patient, while perfectly relaxed at times, as soon as touched the spasms characteristic of tetany were created, with the hands assuming the usual position, wrists flexed and fingers in the well-known position peculiar to the disease, and thumb extending across the palm, strongly adducted almost to the little finger. Both hands were drawn somewhat to the ulnar side. When the spasms were severe the arms would be flexed on the chest. The feet also assumed the characteristic position, being extended and the toes flexed. During the spasm the plantar surfaces became arched and the dorsum prominent. A peculiar feature in this case was that the infant assumed the position of opisthotonos, probably because the muscles of the trunk were involved in the spasm. Trousseau's phenomenon was sometimes present, and the facial phenomenon was well marked. The knee reflexes were greatly exaggerated. There were no symptoms of brain pressure. The diagnosis of tetany was made because of the exaggerated reflexes, the bilateral spasm which could be excited or increased by pressure on the nerves, no loss of consciousness, and the presence of gastrointestinal disturbance. The infant was placed on oatmeal, and later hominy, etc., with a dose of castor oil and calomel every day. At the end of one week the child was practically well. The mother, however, neglected the instructions given her and the convulsions came on again. Dr. Dana had confirmed the diagnosis.

A Case of Cerebrospinal Syphilis.—Dr. KAUFMAN SCHLIVEK presented a boy, eleven years old. The father had an ulcer on his penis when the mother was pregnant with this child about four months. He was treated with mercurial inunctions. When four weeks old the baby had what was probably a specific epiphysitis, and was treated with mercurial ointments. His present illness began about three years ago with a gradual onset. He became listless, could not find his way home, ate food from barrels, complained of headache and poor vision, and always pointed to one spot on the top of his head as being very painful. When the headaches were severe he vomited frequently. He looked like an imbecile. The skull was very sensitive to pressure and percussion. The left pupil was larger than the right; both pupils reacted to light. The tongue protruded to the right. The hands and feet were cold and cyanotic. The skin over the dorsum of the second phalanx of three fingers was infiltrated. There was a double pes planus. The gait was slightly spastic and waddling. There was no ataxia. The knee jerks were markedly exaggerated, and there was ankle clonus. The Wassermann and Noguchi tests were strongly positive. Without the serum tests the diagnosis would have been very uncertain. The prognosis was bad, for the lesion was of a sclerotic condition, and the patient had not responded to treatment.

Gonococcus Vulvovaginitis in Children, with Results of the Vaccine Therapy in Out-Patients.—Dr. B. WALLACE HAMILTON read this paper. During the past three years a careful record had been kept of these cases referred to the Vanderbilt Clinic. There were 344 cases observed, the average age being 5.1 years. There were 151 cases under the age of five, and 193 cases over this age. Strangely enough there were but four cases of ophthalmia from autoinfection. There were 260 cases treated by irrigation; 158 were cured, 53 not cured, 49 lost. There were 84 cases treated with the vaccines; 76 were cured, five were not cured, three were lost, giving a percentage of 90. The average length of time under active treatment by the irrigation method was 10.1 months; by the vaccine treatment, 1.7 months. The five cases that were not cured by the vaccine treatment were all over five years of age, two being over nine. Three cures were obtained in young infants under one year of age, the youngest being three weeks old. In conclusion Dr. Hamilton said that vaccine therapy had a place in the treatment of this affection in little children for the following reasons: (1) The short time required for a cure in over 85 per cent. of the cases. (2) The ease of administration of the vaccine; no special apparatus or knowledge of technique being required. (3) The vaccine was apparently harmless when used under aseptic precautions. (4) It was not necessary to take the opsonic index, with its complicated technique. (5) It eliminated irrigations which directed the child's attention to its genitals, which at times encouraged precocious masturbation. The frequent douches necessary in the irrigation treatment would, with the best care and gentleness, produce some injury when continued over a long period of time.

Dr. GODFREY R. PISEK said that vulvovaginitis was such a bugbear to those who did much work in the hospitals that they were very glad to have such a paper showing the results, especially consecutive results, because heretofore their time had been almost wasted in the treatment of these cases. He had used the vaccines in the treatment of this condition and probably he had used all the irrigation treatments mentioned and a few others as well, with no success in the great majority of the cases. He never felt that any of the cases were absolutely cured; even in those cases where the child was discharged as cured, basing this statement on the smears made, he felt that in after months or years the gonococcus would again be found. Cures should never be recorded until the patients were examined one or two years after treatment. Every girl who entered the hospital had a smear made before admission, as well as subsequently. In the way of prophylaxis, the argyrol ointment and suppositories were used, even though there was no discharge. Such children went through the hospital without becoming contaminated. He had employed

in children as much as five million dead bacteria at once and he had never seen any bad results from such a large dose.

Dr. L. E. La Fétra said he had seen most of these cases and confirmed what Dr. Hamilton had stated in regard to the satisfactory results obtained from the vaccine treatment. For three years at the Vanderbilt Clinic all forms of irrigation treatment had been employed, and finally Dr. Hamilton had resorted to the vaccine treatment for the first time in dispensary patients, and with extremely satisfactory results. About 80 per cent. appeared to be cured. This treatment offered a new hope for these patients who heretofore had proved trying accumulations for any clinic.

On Preliminary Examination of Children at the Dispensary, as a Means of Protection Against Contagious Diseases.—Dr. Sara Welt-Kakels read this paper and offered the following conclusions: (1) There was at present an evident lack of prophylaxis in handling contagious diseases at the dispensary. (2) As at present conducted, dispensaries contributed to the dissemination of infectious diseases among the poor, by contact infection in the common waiting room. (3) If not entirely eliminated the danger of infection was lessened by the preliminary inspection of children, a prophylactic measure, which aimed at an early detection and exclusion of contagious cases and "suspects" before entering the common waiting room. (4) Preliminary examination had been conducted at the Mount Sinai Hospital Dispensary since April, 1907, with satisfactory results. (5) Its establishment in similar institutions was required as a sanitary safeguard and on the ground of public economy.

Dr. Godfrey R. Pisek said that every precaution should be taken to prevent the spread of infectious diseases in the dispensaries. It was very difficult, however, to exclude such diseases as scarlet fever, especially in the early stages, by merely a cursory examination. Most of the dispensaries had common drinking cups; the use of these should be condemned.

Dr. F. L. Wachenheim said that there were some details which Dr. Welt-Kakels had not had time to go into sufficiently. The examination of the throats of all the children was made very carefully, and especially were they on the lookout for Koplik's spots; if a child had any redness of the throat, the chest was examined. These examinations were made by the house staff, and it was rather interesting to note that in January and July, when a new member of the staff entered upon duty, some cases slipped through; but as time went on, there were fewer and fewer that got through their hands. The spread of pertussis could not be stopped in the dispensary. It seemed strange to him that more dispensaries had not adopted such a plan as was now in vogue at Mount Sinai Dispensary.

Helminthiasis in Children.—Dr. Oscar M. Schloss presented a summary of his investigations undertaken to determine the following: (1) The frequency with which intestinal worms were harbored by children between two and twelve years of age. (2) The species of parasite harbored and the relative frequency of their occurrence. (3) The number of cases in which the common intestinal worms were responsible for symptoms, and the nature of the symptoms produced. (4) The occurrence and significance of eosinophilia in infections with the common intestinal worms. He had examined 310 children and, for purposes of convenience, he divided them into two groups, one of 30, the other of 280. The first group was made up entirely on the basis of suspicious symptoms and was of little statistical importance. The second group of examinations were made as nearly consecutive as possible with reference to the presence or absence of symptoms, and 80, or 28.57 per cent. of the children harbored intestinal worms. There were 31 cases of infection with the whip worm without symptoms. In the cases of the other parasites the most common nervous symptoms were restlessness at night, night cries, and general irritability. The gastrointestinal symptoms varied with the parasite. In the cases which presented symptoms, the eosinophile cells were usually above 6 per cent. with the exception of the long-standing infections. In the cases without symptoms, eosinophilia was absent. The only satisfactory means of diagnosis of intestinal worms was the detection of the parasite in the stools.

Dr. Godfrey R. Pisek asked in regard to the nationalities of most of the cases, and what relationship the parasites bore to the food ingested; also what data Dr. Schloss had in regard to contact of the infected children with domesticated animals. The cases always had an albumin loss eventually producing anemia; the parasites also could act as foreign bodies, often invading the appendix, or they might be vomited; again they produced a toxin which no doubt accounted for very many of the reflex symptoms.

Dr. Schloss, in answer to Dr. Pisek's questions, said that there were not more than ten or fifteen of foreign birth among the patients he reported, although about one-quarter of them were of foreign parentage. It was well known that the common tape worm was transmitted by the so-called "measly beef." An infected water supply might be the means, however, of the spread of other parasites. He said he had not examined domesticated animals for the parasites. The most common means of transmission of the common intestinal worm was through the ova passed in the feces of infected patients.

Cerebrospinal Meningitis in an Infant Two Months Old.—Dr. Louis Fischer reported this case and presented the patient. The chief symptoms were the following: The sudden onset with vomiting; loss of appetite in an otherwise normal breast-fed infant; rigidity of the extremities and convulsive movements; anterior fontanelle open one-half an inch and slightly bulging; posterior fontanelle closed; pupils equal but reacting sluggishly to accommodation and to light. Three successive lumbar punctures were made with dry tappings; because of this and the symptoms of rigidity, opisthotonos, fever, and twitchings it was decided to tap the lateral ventricles, about 15 c.c. of a turbid fluid containing pus were withdrawn. The smears showed intracellular Gram negative meningococci. The ventricles were irrigated with normal saline solution and 25 c.c. of antimeningitis serum were slowly injected into the ventricles. This procedure was repeated. The amount of serum injected altogether was about 100 c.c. The child was brought to the hospital October 2, and was discharged cured December 16. The quantity of serum injected should never exceed the quantity drained. The success in this case was due to persistence in the method outlined, to the removal of a sufficient quantity of the purulent fluid within the brain, and to the injection of the serum.

Dr. Simon Flexner said that the case presented by Dr. Fischer was the first example of recovery in epidemic cerebrospinal meningitis that came to his knowledge in which there was an impassible obstruction at the foramen of Majendie and in which a purulent exudate was proven to be present in the ventricles. The recovery in this instance was attributed to the use of the antimeningococcus serum, and he thought it was fair to attribute the recovery to it. While they were all glad to accept the case as proof that recovery did follow the administration of the serum, yet it was not impossible that the washing out of the ventricles might have contributed to the favorable result; there had been several instances recorded in which the ventricles had been tapped and serum injected; but Dr. Fischer's case was the first that had terminated in recovery. Dr. Cushing had had a case that ended in death; Dr. Knox of Baltimore had also had a fatal case, and Dr.

Netter of Paris reported another case, and this patient died. A very striking thing was that such a considerable operation could be carried out in these young children and without any danger so far as he knew from the half dozen cases recorded; there had been no ill effects from the intraventricular injections. It was very hopeful, therefore, to see such a splendid recovery and to think that possibly some of the cases of obstruction which formerly terminated fatally might now be saved. One could speculate on how the communication between the ventricles and the subdural space was re-established; and conclude that the foramen of Majendie became again patent. It was also possible that the formen of Luschka contributed to the re-establishment of communication, but for the present this was merely speculation. Perhaps at some time an opportunity would be presented to make observations that would clear the point up.

Dr. Alfred N. Strouse said that the case was of special interest to him because of the presence of an amblyopia which was unassociated with any perceptible changes in the media and fundus. Careful and repeated examinations failed to disclose the slightest evidence of an edema or swelling of the nerve, or retinal congestion. In fact, the examination was purely negative.

Dr. Samuel J. Kopetzky said that in otitic meningitis he had performed intraventricular puncture with a resulting cure, but his mode of procedure was different; he perforated the ventricle through the tegmen cellulæ of the mastoid process. When the ventricle was distended with fluid it was easily reached; the needle was passed through in a slanting direction for from four to six centimeters. Tapping the ventricle through the fontanelle could be done in an infant; but in older patients with meningitis from whatever source the ventricle could be tapped through either of the other routes, and the required amount of liquid withdrawn and quicker results would be obtained than if an attempt was made to obtain the fluid through the spinal column. The advantages of ventricular puncture in the cases which gave "dry" taps from the spinal column were so obvious as hardly to need comment.

Dr. Louis Fischer said that the case presented was not the first in which he had employed intraventricular injections. An infant seven weeks old had symptoms of cerebrospinal meningitis; after a series of lumbar punctures, resulting in "dry" taps, the ventricles were punctured and pus containing the meningococcus was found. The ventricles were irrigated and the serum was injected. The patient lived thirty-six days. These two patients were very young and, therefore, it was made possible, because of the open fontanelles, to utilize them for diagnosis as well as for treatment. When "dry" taps were obtained, after entering several interspaces, and if the meningeal symptoms plus the bulging fontanelle continued, then one was justified in tapping the ventricles; if in an infant, through the open fontanelle; if the fontanelle was closed, then the Kocher method of entering the skull should be chosen.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held March 24, 1910.

Dr. S. M. Brickner in the Chair.

Uterine Tumor with Bilateral Ovarian Tumors.—Dr. Herman J. Boldt presented a number of specimens. The first was removed from a woman, thirty-four years old, who complained of nothing else than abdominal distention which had gradually increased during the last three years. The abdomen was very prominent; it seemed as though a little withered woman less than four feet in height were attached behind it. Although the abdomen was distended by a tumor practically up to the diaphragm, there was no interference with respiration. A tentative diagnosis of uterine tumor with malignant changes and ovarian tumor was made. The operation was difficult, particularly the extirpation of the cervix, which was deemed essential because of the clinical diagnosis of probable malignancy of the uterine tumor. The pathologist reported the growths to be subserous fibromyoma, papillary cystoma, and double hematosalpinx. After the operation the patient improved markedly.

Fibroid Tumor of the Ovary.—This specimen was removed from a woman, forty-five years old. Her abdomen was greatly distended with ascitic fluid, and she complained of pain in the lower abdomen. The clinical diagnosis was that the large amount of ascites was caused by a pedunculated fibroid, which was freely movable and caused peritoneal irritation. This growth, however, proved to be a fibroid tumor of the left ovary. Whether any degeneration had taken place or not must be determined by the pathologist, who had not yet reported upon it.

Other specimens presented were of a fibromyomatous uterus, a large ovarian cyst mistaken for pregnancy, a dermoid tumor with twisted pedicle, a uterus with adnexa removed by abdominal section, a papillary cystoma of the ovary, a dermoid tumor complicating pregnancy at the third month, a large cystadenoma of the ovary, and a myomatous uterus. Dr. Boldt also showed a uterus and adnexa which were removed per vaginam because of recurrent attacks of pelvic peritonitis and menorrhagia. The patient was forty years old, had been ill for several years, and had been treated without beneficial result. The pathological change consisted in an increase of the connective tissue and a thickening of the blood-vessels.

Hematosalpinx.—Dr. C. C. Sichel presented this specimen, removed from a woman forty-one years old. She complained of pain in the right side of her abdomen which shot down her right leg. Upon opening the abdomen he found a pedunculated hematosalpinx which probably contained water at first and later blood. The growth was twisted six or more times. The patient made a good recovery. Dr. Sichel also presented two specimens of pyosalpinx and one of ectopic gestation.

A Catheterizing Cystourethroscope.—Dr. Leo Buerger presented this instrument.

An Improved Modified Kelly Cystoscope.—Dr. H. D. Furniss presented this instrument.

Functional Disorders of the Bladder in the Female Simulating Cystitis.—Dr. Arthur Stein said that it was no infrequent occurrence to have women make the statement that they had bladder symptoms of some sort, consisting usually in frequent and painful micturition, and at times they stated that the pain occurred before, during, or after emptying the bladder, or that the pains were more marked during the menstrual period. These women had already been treated by their physician who concluded that, from the subjective symptoms, they had a cystitis. A great many ailments situated outside the bladder could give symptoms which correspond to those of a cystitis. The general practitioners, as a rule, believed that a cystitis must be present whenever there was a frequent desire to urinate. Dr. Stein thought, therefore, that it might be of interest to review those conditions in the female which could cause bladder symptoms without a true cystitis being present. He made three subdivisions: (1) The cases in which there was some pathological change or irritation of the nerve center of the bladder wall itself. (2) The cases in which there was some pathological change in the genital organs. (3) The cases in which they were dealing with some general nervous trouble or systemic disease. Certain anatomical facts taught that they were dealing with an independent center in the bladder or with bladder ganglia; changes here must, therefore, cause symptoms resembling those of a true cystitis, although the latter was actually absent. Many of the so-called hysterical bladder symp-

toms were of neuritic origin; these patients should have their attention distracted from the bladder by psychical and general treatment. Under the first subdivision Dr. Stein included those cases in which the bladder was irritated by chemical changes in the urine, with typical symptoms of cystitis resulting. In his second subdivision, in which there was some pathological change in the genital organs, he carefully examined the histories of 54 patients; 30, or 55.5 per cent., made no reference to the bladder; 18, or 33.6 per cent., complained of urinary symptoms which were found not to be due to changes in the bladder itself; only in 6, or 11.1 per cent., were the symptoms due to inflammatory conditions in the bladder. In other words, one-third of the women seeking advice for some gynecological trouble complained of urinary symptoms, though no real disease of the bladder was present. The menstrual period might be accompanied with bladder symptoms, because the bladder took part in the general congestion that occurred at this time. A careful analysis of the pains during urination was most important. If they occurred before urination and diminished during the act, this pointed to a true cystitis; if they were most marked during urination urethritis was the most likely diagnosis; when the pains were referred to the lower portion of the abdomen, occurring immediately after urination, and continuing for some time, the peritoneum was probably involved. Among 1,674 cases of myoma Kelly and Cullen found an increased desire to urinate in 109, or 6.5 per cent. In 20 cases there was a partial or complete retention of urine; in seven there was partial or complete incontinence; in only two was there a true cystitis present. A retroflexed pregnant or non-pregnant uterus, hematoceles, ovarian cysts, and cystoceles might all mechanically cause bladder symptoms of various kinds. An anteposition of the uterus, and a retroflexioversion had the same effect on the bladder as a retroflexion. A carcinoma of the uterus which was beginning to involve the perivesical tissue would give rise to bladder symptoms. Tumors, malpositions of the uterus, cystoceles, inflammations, etc., caused frequent or painful urination when they did not cause bladder symptoms. In his third subdivision, cases in which they were dealing with some general nervous or systemic troubles, he believed that the expression hysteria and irritable bladder should be avoided, for they could nearly all be explained on some anatomical basis. A few, however, would have to be classed as hysteria. He felt certain that most bladder symptoms which were called hysterical were in reality due to inflammatory processes in the pelvis. Under this subdivision he also included those cases of so-called reflex incontinence which was caused by masturbation, by a hypertrophied clitoris, or by a thickened hymen. Many of these cases were still diagnosed as hysteria or even as cystitis. About 50 per cent. of all tabetic patients had distinct bladder symptoms and, as a matter of fact, they were among the initial symptoms of the disease. The patients complained of a frequent desire to urinate, of unpleasant sensations during micturition, and occasionally of pollakiuria. In progressive paralyses they also encountered similar symptoms. Compression myelitis, multiple sclerosis, syringomyelia, and tumors of the vertebral column might all cause bladder symptoms; also, cortical lesions and those of the crossed pyramidal tracts. Dr. Stein ended his paper by referring to various kinds of general poisoning which had an influence upon the bladder. He trusted that he had made it clear that every bladder symptom, whether it was painful urination, frequent desire to urinate, or purulent urine, was not necessarily due to a cystitis. Bladder disturbances might be due to various diseases and often they were the symptoms of a most grave systemic disease.

Dr. W. Gill Wylie emphasized the importance of making a correct diagnosis. Many of these cases were treated as disease of the bladder, the subjective symptoms from the bladder leading to the making of this mistake. In private practice they had the most trouble from the gonococcus infections; they should not be interfered with except when absolutely necessary.

Dr. Herman J. Boldt said that if one took the trouble to reexamine these patients a large number that complained of bladder symptoms would be found to have no pathological lesion demonstrable by the cystoscope. In that particular class of cases that give symptoms referable to the base of the bladder, overdistending the bladder with boric acid solution or even water gave the best results, especially when combined with what he termed vibration of the neck of the bladder.

Dr. Gustave Siligman said that he had been astonished to find at operation how often they found the bladder involved from the abdominal side; often there was an involvement of the bladder by carcinoma which grew towards the bladder and without giving bladder symptoms. He asked regarding the frequency of urination, not at the end of pregnancy but at the beginning.

Dr. Brooks H. Wells believed that the crux of the whole matter was the importance of diagnosis; this was important not only in diseases of the bladder, but in every department of gynecology and obstetrics. To make a diagnosis of cystitis in women it was not only necessary to make a bimanual examination of the patient, but also to make use of the microscope, the cystoscope, and the ureteral catheter. They then would be in a position to make an intelligent diagnosis and state if there was anything which produced tension on the bladder, or if there was anything present which might produce congestion, or cause pain in the adjacent structures, in the rectum, parametrium, tubes, or ovaries which might cause bladder symptoms. A short time ago he saw a woman who complained of frequent micturition, and a diagnosis of cystitis was made. An examination of the urine, however, proved it to be absolutely normal. The cystoscope showed a normal bladder. The bimanual examination revealed the presence of extensive adhesions posterior to the uterus. He thought that the frequent micturitions were caused, not by any cystitis, but by these adhesions, yet he was not satisfied with this diagnosis. Through somebody's advice she tried the wearing of a rubber band and then she found she did not have to urinate so frequently. Dr. Wells' point was that often when they thought there was some organic or physical condition at the base of the bladder to account for its irritability they might have a mental or psychical condition behind it which should not be overlooked.

Dr. H. D. Furniss said he had seen two or three cases of carcinoma of the bladder, an extension of the disease from the uterus, which caused no bladder symptoms. Retroversion of the uterus causing bladder disturbances was often mentioned, but in the majority of the cases one would find a coexisting urethritis. He said he had come to the conclusion that in many cases of retroverted uteri, of pelvic adhesions, and urethritis the cause was the same, usually the gonococci. When cystitis was encountered it was his belief that it was a complication, often of kidney origin, due to a pyelitis, a pyelonephritis, or stone. He had recently seen two cases of severe cystitis due to trouble in the kidney; in both cases there was found a mild pyelitis due to an upward extension.

Dr. Robert L. Dickinson said that the use of the cystoscope had given practitioners the ability to make a diagnosis, but had not offered much in the way of treatment perhaps. Among the more common conditions that were not cystic, but caused bladder symptoms, the question of residual urine was a matter worthy of consideration. Also varicosities, at the base of the bladder, and erotism would also cause bladder irritability. He believed

that this principle might be enunciated concerning outside tumors, growths, and inflammations, that one could do almost anything to any part of the bladder as long as they left its base alone.

Dr. Leo Buerger said that not long ago he saw a patient who interested him very much. She was an erotic, nervous woman, and had been operated upon three years before, and had been catheterized for the first time. Ever since she had complained of bladder symptoms. The cystoscope revealed nothing. She urinated every two hours, and often every hour. Two years after the operation she urinated every fifteen minutes, with the urine perfectly normal. The cystoscope was again used, and he found on either side of the trigone small granulations, which he cauterized with an electric cautery, then gave gradual dilatation, and after four weeks' treatment she was perfectly well and had remained well ever since. This case simply showed how a small lesion could give rise to such symptoms when, under ordinary circumstances, it should give rise to none at all.

Dr. Arthur Stein said that the term irritable bladder meant nothing, and the expression should be dropped. One should go back to the changes in the nervous system to obtain a suitable term for the condition. He agreed with what was said about adhesions; but there were many cases he had seen in which he could not find any other trouble. With regard to the frequency of urination at the beginning of pregnancy, he thought that the increased blood supply to the pelvic organs at this period was responsible for this more than the increased nervous reflexes.

Philadelphia Neurological Society.

At a stated meeting held March 25, Dr. Philip F. Williams presented a colored man who was rather suddenly seized with weakness in the left upper extremity and the development of asteroegnosis. Under emotional influences the phenomena disappeared, but they gradually reappeared in somewhat lesser degree. Dr. Williams exhibited also a patient with weakness and increased reflexes in the left lower extremity and various disturbances of sensibility in the right lower extremity. Dr. Alfred Gordon exhibited "A Case of Brain-Lesion or Brain-Malformatoin in a Boy of Eight." Enlargement of the head had been observed in childhood, with the development of epileptic convulsions of varying frequency and severity. The head was dome-shaped and the eyes were prominent. Intelligence was average. Nystagmus was present and also optic atrophy. *X*-ray examination disclosed great thickening of the cranial bones, with excavations on the inner table into which the convolutions fitted snugly. Dr. Gordon exhibited also "A Case of Bitemporal Hemianopsia followed by Optic Atrophy of Traumatic Origin." The patient was a man who had fallen a considerable distance, with the appearance of symptoms of fracture at the base of the skull. He presented bilateral optic atrophy with temporal hemianopsia and deafness on one side. Drs. J. T. Rugh and J. Hendrie Lloyd presented "A Case of Muscular Dystrophy with Hemophilia." The patient was a young man, 21 years old, who since the age of four years had had repeated attacks of rheumatoid character with articular swelling and fever, frequent hemorrhages from the mucous membranes and beneath the skin, wasting in the lower extremities, absence of the knee-jerks and extensor contracture of the right foot. The affection was thought to be due to derangement of some internal secretion. Dr. Augustus A. Eshner presented "A Case of Total Ophthalmoplegia, with Bilateral Facial Palsy." The patient was a man, 45 years old, who shortly after exposure to draft noticed lacrimation, diplopia, and pains about the face and head. On examination the eyes were found staring and capable of little movement in any direction, with pupillary reaction to light, but deficient reaction in accommodation and convergence. Facial movements were greatly restricted and there was difficulty in closing the eyes and opening the mouth. Mastication was embarrassed and speech was interfered with. Sensibility was preserved. Other than pallor of the discs there was no noteworthy change in the fundus oculi. The condition was thought to be due to disease of the nuclei of the third, fourth, sixth, and seventh nerves, probably of infective origin. A certain measure of improvement in the movements of the facial muscles had taken place under treatment with mercuric chloride and potassium iodid, although there was no history of syphilis. Dr. Wm. G. Spiller presented a communication entitled "Conjugate Deviation of the Head and Eyes in Cerebellar Lesions." He pointed out that in connection with cerebral lesions deviation of the head and eyes toward the seat of the lesion and away from the paralysis is the rule, but he knew of no observations as to the character of the deviation, if any, in cases of cerebellar lesions. He had observed a case in which in addition to hemorrhage into the right cerebral hemisphere, with paralysis of the left side of the body, there was also a lesion of the left cerebellar lobe, with deviation of the head and eyes toward the side of the latter lesion and in the direction of the paralysis. Dr. Edward Mercur Williams reported "Three Cases of Rhizomelic Spondylosis," in one of which the symptoms were of syringomyelic type, that is with spastic paralysis and wasting on one side and sensory dissociation on the opposite side. Dr. John H. W. Rhein read a paper entitled "A Case of Congenital Hemiplegia with General Choreiform Movements," in which post-mortem examination disclosed a rather diminutive brain, with an absence of ganglion cells in parts of the anterior horns of the spinal cord. Dr. Rhein also exhibited "A Specimen from a Case of Tumor of the Pons." The clinical course was characterized by an irregular evolution, with oclar and other palsies, making the diagnosis exceedingly difficult. Post-mortem examination disclosed a new growth surrounding and involving the pons. Dr. Albert C. Buckley presented "A Case of Associated Psychosis and Spinal Cord Disease." The patient was a man of scientific training, who presented varied delusions, together with symptoms of lateral sclerosis and with slightly narrowed somewhat sluggish pupils. Venereal infection was denied. The association was thought to be an accidental one. The society adopted a minute on the death of Dr. Wharton Sinkler, one of its founders.

Pathological Society of Philadelphia.

At a stated meeting held January 27 Dr. Milton B. Hartzell exhibited "Sections of Granuloma Annulare." This is a somewhat uncommon disorder, variously designated, appearing on the extremities as a circle of papules and characterized by cellular infiltration and mucoid degeneration. Dr. John Funke exhibited a specimen of "Cyst of the Frontal Lobe." The patient was a young woman who for three years had been having fainting attacks without loss of consciousness. The exact nature of the cyst had not been determined. Hooklets were not found in the contents, but cholesterin was present in the lining of the walls. Dr. Funke exhibited also a specimen of "Sarcoma of the Frontal Lobe" on the right side, and another of a similar growth on the left side. In both cases there had been headache with nausea and vomiting. Dr. Funke exhibited also a specimen presenting the histologic characters of "Cylindroma of the Brain," and also one of "Gliosarcoma of the Pontine Angle." Dr. Joseph McFarland exhibited a specimen of apple-worm obtained from the nostrils of a patient suffering from pulmonary tuberculosis. The localization was to be explained through the expulsive effect of cough on food in process of deglutition. Dr. H. T. Karsner exhibited sections of "Fibroma of the Kidney" from a case of general adiposis and multiple lipo-

mata, and also sections from a case of dermoid cyst containing tissues of stomach and bowel. Drs. E. C. Hirst and B. S. Veeder reported "A Case of Pancreatic Cyst" successfully extirpated, and they described at length the chemical characters of the contained fluid and the histologic structure of the sac. The formation was thought to be a retention cyst. Drs. Leo Loeb and M. S. Fleisher presented a communication entitled "Absorption from the Peritoneal Cavity." They reported the results of three years' experimental study from which they concluded that the use of such agents as adrenalin and digitalis acted not so much by causing absorption of fluid effused into the peritoneal cavity as by preventing further effusion.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of April 23, 1910:

	Cases	Deaths
Tuberculosis Pulmonalis	858	185
Diptheria	546	50
Measles	1,317	33
Scarlet Fever	783	31
Smallpox	4	1
Varicella	122	—
Typhoid Fever	23	5
Whooping Cough	42	4
Cerebrospinal Meningitis	11	12
Malarial Fever	—	—
Totals	3,706	321

The compulsory State system of sickness insurance instituted in 1884 in Germany has proved a powerful factor in combating tuberculosis. No less powerful have been the public sanatoria, the number of beds in which have increased during the past fifteen years from 243 to 8,422. Of the 200 tuberculosis sanatoria and hospitals in Germany, 35 are supported by the carriers of sickness insurance. The statistics of the Imperial insurance department show, that as many as 42 per cent. of the number of persons treated in these institutions remained in good working health five years after being dismissed from the sanatorium.

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended April 22, 1910:

CELLULAR ACTIVITY; THE EPITOME OF RATIONAL MEDICINE.

WITH ILLUSTRATIVE CASES.

By MARGARET A. CLEAVES, M.D.,

NEW YORK.

A RETROSPECTIVE analysis of the cases of our unphysiological contingent is as illuminating as the retrospective analysis of life. Given the requisite fundamental grounding, experience is ever the best of teachers. In the care of chronic conditions, covering the entire range of medicine as known under a diffuse and varied nomenclature, the concept of the cell, the relation of cellular activity to normal chemicophysical action, its disturbances whether manifested in a pathological physiology or an actual pathological lesion, changing anatomical characteristics as well as physiological function, must ever be to the fore.

In disturbed or disorganized cellular activity is epitomized the whole story of rational medicine. It does not matter what expression of unphysiologic condition is taken on, whether a hysteroepilepsy, an epilepsy, a manic-depressive insanity, a melancholia, a neurasthenia, a neuritis, a rheumatism, a rhinitis, tonsillitis, bronchitis, pneumonia, a chronic nephritis, a hepatitis, a gastroenteritis or an enteritis, an endometritis, salpingitis, a uterine atrophy, hyperplasia, fibroid, or hemorrhage, a cystic ovary, an appendicitis, a degenerative moral change, not even excepting pregnancy and childbirth; the fundamental truth remains the same.

The manifestations of disturbed cellular activities are like the evils of Pandora's box in their multiplicity and incongruity. The physician's duty lies in relating them to the fundamental truth and in caring for them with the breadth of therapeutic horizon inculcated by the point of view. That physician is best equipped for his work, whether as attendant or consultant, call him what you will—an internist, a surgeon, a neurologist, a psychiatrist, an obstetrician, or a rhinologist—who possesses this comprehensive outlook. No narrower vision will suffice for successful therapy.

In this twentieth century disturbed cellular activity is very prone to manifest itself in disturbed function of nerve and brain. But as that thought leaves my pen, I am reminded of the endless series of cases, subjected to the minute qualitative, quantitative, and microscopical examination of the highly specialized laboratorian, with the telltale evidence of degenerative visceral changes, especially in the kidneys. It is in this way that the integrity of cellular activity is ever guarded, as well as by the full insignia of clinical evidence.

The concept of the vital integrity of the cell points with etiological finger to the anguished dread of mankind—cancer.

In the rôle of cellular activity there is no uncertain note; it is the cell which in its myriads keep up life's ceaseless activity. Again, if we accept the theory of a well-known physicist, it is the cell freed from all its struggles with impurities which is the seat of the soul and which takes on immortality as a soul particle or *psychomere* in the radiance above and beyond our earth-bound lives.

To be earth-bound: The story is told in living bronze, the work of a creative genius, but it is told equally in the tortured nerve, the congested and confused brain, the thickened and irritated skin, the painful and creaking joint, the swollen, sensitive muscle, the engorged liver, the weakened kidneys, the irritable, palpitating, and irregular heart, the heaviness, eructations, flatulence, the disordered function of the entire gastrointestinal tract, the inflammations with their serous and purulent effusions, their organized exudates, and likewise in the uncertain, irritable tempers of the unphysiological contingent.

Earth-bound, because of the struggle of the cell to meet the demand laid upon its chemism by the individual. That nerves, brain, skin, muscle, joints, organs, whether vital or not, cry out is because cellular activity is disturbed or degenerating. The clean-cut cellular activities of physiological lives are transcended by reason of a disproportion between agent, reagent, and energy values.

The struggle of the cell with untoward toxic conditions comes not of necessity from ingestion of too much or wrong assimilable material, although far too often such is the cause. Its normal function is prejudiced as well by all the conditions of life; anxious care, worry, grief, fatigue, wrong habits, lack of fresh air, lack of radiance, changes in barometric pressure, atmospheric and electrical conditions, rarely by overwork, but often by too constant work without change. The story receives its final, not its first, expression in organs. In fundamental physiological activity of the cell is to be found health; in its aberrations the rational explanation of disease.

The best, speediest, and most lasting results are to be obtained by full recognition of all the influences potent etiologically. Only then can all the therapist's forces be marshaled in such a way as to make every agent, whether mental, moral, or physical, do effective work. It is necessary that there should be an intelligent and discriminative use of all means of stimuli tending to the production of physiological cell activity. In this way only can the bloodstream approximate, reach, or be maintained in the purity and richness in red blood corpuscles essential to physiological well being. The wonderful prevision of Shakespeare, ever to the fore, was never more so than when he uttered the

famous line, "The life of all's in the blood." Many a brain has passed under the most careful macroscopical and microscopical examination without revealing any telltale evidence as to why the intelligence had been distraught. With others I ever looked for some definite finger-mark and wondered that I found it not. The influence of life upon a mechanism, which is after all at one with the natural phenomena of the physical world, should never be lost sight of. To this end not only must the value of expenditures of energy be appreciated, but its conservation as well.

As a result of life's activities there comes to be in a greater degree to some than others, markedly diminished energy values. To the end of the best for the individual this must be reckoned with and nature's forces conserved. It is the careful examination of end products that tells the story of cellular activities and ever elucidates the case. Especially is this true in nerve and mental conditions where the influence of a toxic and irregularly circulating bloodstream prejudices the viewpoint of the ego, rendering the patient's record of symptoms of doubtful value. In the vitiation and pollution of the bloodstream is to be found the prolific cause of human anguish; in its purity and radiance the joy, uplift, and beauty of life.

The following cases are quoted as illustrative of accomplished work: May 14, 1908.—Miss D., æt. 51, teacher. Hysteroepilepsy, duration five years; seizures from two to fifteen months apart. A six months' holiday in Europe was unquestionably an influence in the longer interval. Menstruation irregular. No pelvic pain. Constipation for most of adult life. Under my care in 1890 for an endometritis and salpingitis with right lateral posterior displacement, characterized by excessive purulent discharge of more or less periodicity and by dysmenorrhea; constipation; nerve weariness. Surgical intervention strongly advised by former attendants. Pelvic symptoms dated from an attack of scarlet fever in early menstrual life. Parents tuberculous and patient had pulmonary hemorrhages as a young woman. She recovered under conservative treatment and able to keep constantly at work. For thirteen years I was in touch with the patient, but for five years preceding May of 1908, a change in our addresses made it difficult for her to come to me for advice. From March, 1903, to May, 1908, she had had thirteen seizures, varying in severity.

Characteristics: Time of occurrence nocturnal or early morning; unconscious; apt to be found on floor by bedside in the morning; involuntary discharge of urine; loss of memory; more or less aphasia; speech thickened; difficult cerebration on return to consciousness; disturbed circulation; face greatly congested at time of attack—almost purple; impaired motor power for several days to several weeks after an attack and able to walk only by aid of a cane. Also conscious of sense of weakness in facial muscles; no loss of power, however. The attacks were followed by loss of weight, especially about hips.

Mental condition following attack: Increased impairment of memory; cerebration slow; concentration impossible; great fear of being alone; sense of dread and impending danger; usually most courageous.

Physical examination: Inspection; countenance worn and anxious; pallor of skin; sometimes facial flushing. Had aged perceptibly beyond her years. movements lacking in definite precision; speech a little slow; words difficult of recall; circulation impaired; feet, legs, and hands cold. Abdomen normal in outline; percussion note dull over the entire colonic area; constipation. Hypogastrium: No departure from normal; no sensitiveness. Vaginal examination: Right lateroposterior uterine displacement; uterine hyperplasia; congestion of pelvic tissues; tubes normal to feel; no discharge. Menstruation irregular. Attacks preceded or followed the physiological function.

During the years from 1903 to 1908, when I did not see her, she had variously electrical treatment, massage, osteopathic manipulation, and the usual round of suggestive attention.

Attack of May 4, 1908: Ten days prior to visit, attending physician said he could do no more. A gynecologist was consulted, who insisted upon an immediate surgical operation as the only means of relief. Patient came to me for opinion as to need of operation. Urine analysis revealed the presence of albumin, indican, and calcium oxalate. My opinion was that surgical intervention was unnecessary, and conservative measures were advised; prognosis under careful following of advice good. Nature was the kindest physician, but must be intelligently guided and skilfully aided.

Indication: Stimulation of normal cell activity to the end of relieving constipation, improving pelvic, intraabdominal, and visceral circulation. The patient was seen twice a week at first, then once for the first seven weeks, when she left the city for the summer holiday. For the nine months from September 16, 1908, she was seen from once a week to once in two and three weeks. Since September, 1909, has been seen but seven times. Is kept under observation, for preventive work is ever the best. In the almost two years she has had three slight attacks, precipitated in every instance by disturbances of cellular activity, resulting in diminished and erratic energy, constipation, and pelvic congestion. She has taken on extra work happily and has grown younger in looks and feeling.

May 28, 1908.—Mar. V. H., æt. 80. Arteriosclerosis, chronic rhinitis with mucopurulent discharge. Urine exhibited high urea, with trace of albumin and a few casts; reaction for indican very decided; calcium oxalate present; cylindroids. Measures were adopted to free the nasopharyngeal sinuses of mucopurulent secretion, to establish the best circulatory conditions possible in this tract, also in the spinal, intraabdominal, and visceral systems. Diet prescribed.

June 4, 1908.—Urine analysis: Decided drop in specific gravity and urea, with but faint traces of albumin and indican; no casts in centrifugal sediment; no calcium oxalate; no cylindroids. General condition better; less headache; less depression. Treatment discontinued. Reported to show improvement in cellular activity as indicated by urine in a week's time.

November 20, 1909.—Mr. S. L., æt. 45, merchant, married. Four children. Referred by Dr. Allard of Paris. Evidences of disturbed physiological functions for over a year. Fermentative conditions; autointoxication; neurasthenic; impairment of sex function; mental depression; profoundly apprehensive; irritable heart. He had made the usual round of care, baths, and sanatoria in France and Italy.

Urine analysis: Sp. gr. 1034; highly acid; heavy pinkish granular sediment; urea 24.8 grams per litre (10.8 grains per oz.); albumin trace; indican ex-

tremely decided; much sodium urate; occasional cylindroids. Indicanuria with renal congestion.

November 26.—Sp. gr. and urea near normal; albumin faintly persistent; indicanuria entirely cleared up. Under care one week; en route from Paris to the West Indies. Steady improvement, with marked symptomatic relief, not only in function, but in the mental uplift, optimistic outlook, loss of apprehension, buoyancy, and renewed courage. Subsequent advice by letter.

October, 1906.—Mrs. W. L., æt. 45, married at seventeen; has five children. Labors normal save puerperal infection at fourth. Father, mother, brother, and sister dead of degenerative visceral changes. Immediate cause of death in sister, uterine hemorrhage. A family of "good livers" for generations. Patient was well as a child. Health more or less impaired since puerperal infection. Albumin and casts in urine for years. Weak, inefficient, and irritable heart action; irritable nerves, mental depression, apprehensive to a degree of terror; frequent attacks of very marked edema of the eyelids, one or both effectually closing the eye; great photophobia; uterine hemorrhages; disturbed digestion.

Physical examination: Excess of fat, flabby tissues; enlarged and flatulent abdomen; inefficient and irregular heart action. Pelvic examination: Tissues relaxed; circulation disturbed; no abnormalities of position or structure, save enlarged and flabby uterus.

Condition dependent on disturbances of the general circulation. There is neither tone nor elasticity of heart muscle and blood vessels. The patient is subject to attacks of cardiac insufficiency, in which the pulse becomes almost imperceptible; exhaustion profound, even to point of unconsciousness; great pallor; response only to nitroglycerin and strychnine hypodermatically.

During these three years she has had two serious attacks of this sort, requiring energetic measures promptly. None since last June. Urine has been free from albumin and casts save when she has overindulged in eating, been unduly anxious from one of the many causes entering into most lives, and taken insufficient exercise. These periods are always characterized by lessening cellular activity and a taking on of fat. Then albumin and casts will appear again, the heart becomes weak and irregular, flesh flabby, and menstruation excessive to the point of an exhausting hemorrhage; also prolonged. The casts have been of the following types: granular, hyaline, epithelial, and waxy. Condition: Chronic interstitial nephritis; fatty infiltration of the heart.

Present condition: Increased muscular activity; diminished weight; skin clear, eyes bright, tone good; no more attacks of edema of eyelids; nerves less irritable; no mental depression; no longer fearful and apprehensive. Appetite good; digestion good; improved bowel action. Menstrual function continues, but has become irregular. Walks, climbs when in the mountains, drives, motors, goes to theater, opera, and shops. This year has taken up Latin, not touched since school days. The lack of energy value has ever to be reckoned with, but by careful supervision she is living her life happily and well despite her physical handicap and hereditary strain. In the last attack of cardiac weakness, June, 1909, every resource of the physician's art was requisitioned and for three hours I worked, not pausing to remove my hat even.

May, 1907.—Miss J., æt. 63, single. Seen as consultant. Of good birth; always well. A year previously had a great grief, shock and loss of financial support; became profoundly neurasthenic with all the symptoms of nerve irritability, mental anguish, profound depression, sleeplessness, muscular and nerve pains, swollen, hot, and painful hands and feet, disturbed digestive function, almost loss of vision in one eye, much headache. The oculist could find no trouble with the lens; at the same time he denied any albuminuric retinal inflammation. Urine was not examined. Diet and regime not cared for. Condition of eye an albuminuric retinitis or incipient cataract. As I did not see the patient personally, I could not be sure of eye condition.

May 13, 1907.—Urine analysis: Urea 11.5 grams per liter; albumin; indican; hyaline, granular, and epithelial casts; uric acid abundant.

May 27, 1907.—Urea 3.6 grams per liter; faintest trace of albumin; no indican; no casts, save an occasional hyaline; no uric acid; occasional cylindroids.

June 15, 1907.—No casts: faint trace of albumin and indican; no uric acid; an occasional cylindroid.

October 21, 1907.—Only a faint trace of albumin and indican. During preceding four months evanescent lapses from grace.

November 4, 1908.—The last four examinations have been normal in their findings.

Present condition: Is in better health than for over four years. Impairment of vision permanent. Have referred her to Chicago, for further examination of eyes and oculist's opinion. Has diminution of energy value and in overdoing or too constant doing, there is a sense of less well being. The attending physician to whom I sent urine analysis was of the opinion that "a few casts were not of much moment." The few casts seen on a microscope slide, however, represent the irritant action of disturbed cellular activity upon the tubule linings in a single drop of urine only. To estimate the extent of the mischief the number of drops in twenty-four hours must be considered. He also wrote that "as she improved he trusted she would take a less disheartening view of life than she had." Why trust? Stimulate cellular activity; remove the toxic condition and with purity and richness of the bloodstream, the outlook upon life becomes optimistic even though 63 is reached and life's activities in the way of finance have come to naught. The patient looks younger, and was able to cope with great grief, some eight months since, more readily than others in her family; is better poised, less nervous, vision not improved, appetite good, digestion good, goes on well unless she eats excessively or overdoes. Lack of energy is always to be reckoned with.*

March 5, 1908.—Miss A. J., single, æt. 29. Of good family. One child. Referred by Dr. Elwood Worcester, Emanuel Church Movement, through pastor of church, with which patient's family were affiliated. As a child, she was well, but not of alert mentality. Matured at the usual time. Menstruation normal. Gave birth to an illegitimate child six or seven years before consultation. Cared for in private hospital; child given away; never seen by mother, who returned to her home and took up life as the youngest daughter. While active in household duties, in connection with Sunday school and church, singing in the choir, she showed a deficient mentality and a markedly impaired sense of morality. She could not be trusted away from the

*An examination of the urine of patient, made March 24, 1910, shows continued freedom from casts.

home, but as no restraint was imposed other than watchfulness, she often absented herself, visiting the rooms of young men.

To such an extent was this her mode of life, despite the position of the family, that she was practically ostracized and had to give up affiliation with her societies—Daughters of the Revolution for example—and active work in the church. Social recognition was withdrawn. This was her course of conduct up to the time of being placed under care.

She was overheard by the pastor soliciting the organist of the church choir. His interest was awakened and he believed, that, while apparently a case of moral degeneracy, certainly a defective intelligence, an effort should be made to awaken her moral sense. The Emmanuel Church Movement invited his attention, but Dr. Worcester told him to consult me. Under care from March 5, 1908, to June 29, 1908, and in charge of a trained nurse.

Physical examination: Height five feet, seven inches; well built; undue fat but muscular; unprepossessing facial characteristics, speech, and conduct; manner bold and defiant outwardly; a good deal of sensitiveness under her outward boldness. Brow low, skin thickened, oozing oil globules; blackheads and acne spots. Abdomen: Inspection and palpation normal. Percussion dullness over colonic area, especially descending colon; constipation. Hypogastrium: Inspection, palpation, and percussion normal.

Pelvic examination: Tissues about introitus vaginæ bathed with a creamy discharge; labia thickened and reddened; clitoris: intense thickening of all the surrounding tissue; not hooded. Vaginal examination: Ovaries and tubes normal in position and structure. Uterus enlarged, subinvoluted, congested, mucopurulent discharge. No sensitiveness nor pain. Microscopical examination of discharge negative; a gonorrheal infection was suspected.

During the almost three months in the city under care, she gave absolutely no trouble. Daily visits, then five times a week, afterwards four and three times. The best of the therapist's armamentaria was called upon from the chemical, physical, mental, and moral side to the end of establishing normal cellular activities and to the unloading of overburdened cells primarily, tissues and organs secondarily. Great care was taken of every hygienic detail; baths and cold showers were obligatory; diet was supervised; meat cut down to the minimum; local treatment directed to the establishment of the best circulatory conditions; exercise ordered; reading prescribed and carefully overlooked to the awakening of the best of her intelligence.

She was trusted in every way that her sense of moral responsibility should be aroused while the chemism was carrying on its activities and a nontoxic bloodstream was flooding every tissue and organ, above all the brain. There was no preaching, no questioning as to her conduct, no blaming for the past, but ever an attempt to show her the joy and beauty of a physiological life and to help her to know that while nature had endowed her with certain desires, they were not to be met irrespective of her relation to the social fabric.

Improvement in physical condition began at once. Skin cleared up, blackheads and acne spots disappeared, eyes grew brighter, manner became more gentle, appetite good but not overindulged; bowels regular, vaginal discharge greatly diminished and changed to a mucoid nature, and general circulation greatly improved. The urine which was of high specific gravity, high urea and with decided trace of albumin, became normal.

The patient was discharged June 29, 1908, radiant, happy, interested in books to the limit of her intelligence, in the larger world but with a limited horizon.

December 27, 1908.—Letter telling of a useful life; of trust; of the happiest Christmas she had known in years; of the Christmas tree, the dinner, and guests, the pastor of the church and wife, and of being remembered as never before in her life.

July, 1909.—The pastor of the church reported that he had neither heard nor seen anything to cause him to think that she was not all right. She had taken up vocal music; was raising poultry in addition to her household duties. "So far as I can judge," he wrote, "she is very much better than for a long time before she went to you. I see her frequently, almost every Sunday in the church, and often visit at her home." Morals and manners are amenable to the influence of a nontoxic blood as well as aches, ills, and madness.

These are but a few cases from the many in which improved cellular activity is evidenced, not only by the laboratory examinations, but by disappearance of the symptoms due to a toxic bloodstream.

Cases of cerebral congestion, of mental confusion, of melancholia, of neurasthenia, of neuritis, of rheumatism, of uterine hemorrhage, of rectal hemorrhage, of eczema, acne, of chronic cystitis with pus in urine, as well as all the conditions in medicine named as more or less distinct entities, could be detailed. In chronic cystitis the pus has disappeared entirely from the urine without local intervention. In some instances the way to betterment lies in stimulating local cellular activities, in others relief of a local manifestation is established only through a general stimulation of the chemism.

Physiological cleanliness of accessory sinuses and mucous cavities, as well as of the gastrointestinal tract, is imperative. With the latter comes physiological cleanliness of the blood.

The neurasthenia of man as that of woman, which is climacteric, is prone to occur about fifty years, although sometimes its manifestations are earlier in both sexes. The characteristic evidence is to be found in disturbed cellular activity, metabolic depression, autointoxication, and markedly lowered vitality.

It is not necessary to theorize that insufficiency of thyroid, for example, as has been recently done by a French physician* in an analysis of 201 cases, accounts for the climacteric neurasthenia of men, characterized as it is by all the evidences of a poisoned, sodden circulatory stream from disturbed and disordered cellular activities. Nor, again, is there any cause for wonder in the fact that humanity's complement shares alike the phenomena of a definite physiological change as the fourth decade merges into the fifth.

Disturbances of the chemism's normal cellular activity prevents the rhythm of life, diminishing energy values. The diminution of energy value may find its expression in a weakened vitality, or in the more robust in the disruptive and erratic manifestations of the hysteroepileptic.

Woman may forfeit her divine right—motherhood, without so unfortunate a sequel, but only if the best of cellular activity is kept up, especially in

*DeFleury: Bull. de l'Academie de Medécine, December 21, 1909.

the decade that environs her physiological change. The truth remains, however, that the years of unbroken and ever-recurring periodical function, the incessant use of brain rather than body, increases susceptibility to such cyclonic disturbances in the predisposed. Energy has been diverted and in its diversion cellular activity inhibited. On no organ does the blood—an "altogether peculiar juice" as Mephistopheles says in "Faust"—tell more quickly when toxic than on the brain.

Preventive medicine is ever the physician's stronghold, but the complexity of life, the inability of the generations as they succeed one another to profit by the experience of others, will ever keep a vast unphysiological contingent in need of care.

There is no work of greater importance. Great acclaim is the surgeon's, and justly, for his bold, brilliant, decisive initiative in the moment of danger. But in the careful guarding of cellular activities, the need for the surgeon's knife would be markedly lessened, as well as for serum and vaccine therapy. Operations for appendicitis would be reduced to a minimum and infective conditions practically disappear, for through physiological activity of the cell, immunity to the specific bacteria is maintained.

Still further in the disturbances and degenerations, even in their beginning, the best results are to be obtained by the recognition of every known means of stimulating physiological cell activity.

If the response does not come through the agency of one of the many means at the therapist's command for the stimulation of cell activity, still another and yet another must be selected.

The paramount importance of a knowledge of the physical properties and physiological action of the various physiological stimuli, whether chemical, physical, mental or moral, must never be lost sight of.

Success can be attained only by their skilful and discriminating use, often extending over long periods of time.

There is a more brilliant and spectacular side to professional work, but none which, after all, so fully compensates in its influence upon the lives of others as does the physician's careful, painstaking effort toward the perfect and harmonious cellular action of the chemism embodying the ego.

616 Madison Avenue.

THE ACTION OF INTERMITTENT X-RAYS ON GENERAL METABOLISM AND CHRONIC DEGENERATIVE DISEASES OF THE EYE.*

By FINLEY R. COOK, M.D.,

NEW YORK.

In the Medical Record of November 14, 1908, in an article entitled "*X*-ray Flashes, or Intermittent *X*-rays," the writer presented a new method of *x*-ray treatment, which contrasted the regenerative action obtained by intermittent exposures with the degenerative action, which usually followed the use of continuous exposures. The flash treatment which consists in making and breaking the primary current to give a period of rest after each explosive bombardment resulted from futile efforts to maintain a simple stimulative action, in chronic degenerative conditions of the eye, with the routine method of treatment.

*Read before the Academy of Pathological Science, February 25, 1910.

The first attempt to utilize *x*-ray energy in the eye was in February, 1907, when a young lady, aged 27, whose left eye was the seat of a congenital posterior polar cataract, and who was suffering from local pain, associated with a low general vitality, had herself suggested and requested the experiment. Competent oculists had advised against any operative procedure, on account of the arrested development (deficient generation) of the retina and optic nerve, and regarded the case as a hopeless one. After the second or third treatment with systematic continuous exposures, she suddenly experienced relief from the subjective symptoms, and was conscious of an improvement in vision, which gradually continued until at the end of the twelfth treatment she was able to thread a needle and read ordinary print with the eye, in which she had been practically blind from birth. An examination under atropine at this time revealed no change in the cataract and the improvement in vision was attributed to a possible dilatation of the pupil which, however, was not perceptible. Shortly after resuming treatment, the subjective symptoms recurred with a sudden retrogression in vision, and upon dilating the pupil several small areas of cataractous degeneration were noticed in the periphery of the lens. It was evident that a primary stimulating and tonic action had become an irritant and consequently all treatment was abandoned.

Another attempt to relieve blindness with the continuous method was made in the case of an old lady, aged 90, who had been totally blind in the left eye for thirty-five years, and in the right had only perception of light for seven years. The left eye presented a mature senile cataract. The right, a contracted pupil, with an exudate in the lenticular capsule, a cataract having been successfully extracted fifteen years previously, restoring vision, which she held for eight years. The eye with the cataract, being selected for treatment, was exposed through a small opening in a sheet of lead foil, which completely covered the other eye, together with the head and face. Rays of medium intensity, distance of tube 10 inches, amperes 5, time of exposure 5 minutes, constituted the treatment. After removing the lead shield from the protected and supposedly untreated eye, the patient exclaimed that she could see. The pupil was seen to be dilated, the lens capsule was transparent to light, and the fundus showed the red-réflex. She was able to recognize friends at a distance and to find her way with ease. After several weeks' treatment she was able to read ordinary print with the assistance of her convex lens. A pericorneal injection appeared in the eye with the cataract, and it became very sensitive to light. These symptoms persisted after abandoning treatment, and six months later that eye became the seat of an acute exudative inflammation resembling glaucoma, from which she eventually recovered, with no impairment of the vision in the other eye. This case, like the former one, served to demonstrate a dual action of continuous *x*-rays in the eye.

It was now recalled that a number of patients who had received *x*-ray treatment for various conditions had spoken of a relief from eye-strain and of an improvement in vision. Ripening of senile cataracts occurred in several well advanced cases that had been radiated for chronic skin lesions of the face, and in one case in particular it was evident that *x*-rays had fortified the organ for the radical operation.

From this experience it now occurred to us that it might be possible to open a new field for radiant energy in chronic diseases of the eye, if we could form some conception of the general laws which govern the action of more familiar forms of energy in cellular regeneration and degeneration.

When we consider the influence of other forms of energy on metabolism, it is quite apparent that they have a dual action. This action must consist in either an acceleration or inhibition of metabolic processes, for otherwise their action would be negative. But the influence of various types of energy, as chemical, mechanical, light, heat, baterial, and electrical, upon both animal and vegetable cells is equally conducive to both regeneration and degeneration.

For example, a certain amount of heat is essential for animal and vegetable generation, but excessive heat is equally destructive to both. Electrical energy is employed to stimulate and to inhibit cellular function, or to suspend and to resuscitate vital phenomena. Drugs which are sedative in different dosage become stimulant. Bacterial energy so essential to many vital processes plays an important part in tissue necrosis. Under certain conditions we utilize the potential energy of toxines to check degenerate tissue changes, which in turn are the result of the same type of energy. Light is essential for the generation of cells specialized for vision, but too intense or too prolonged exposures induce cellular degenerations.

X-ray energy is certainly no exception to the rule; under certain conditions it promotes metabolism and stimulates cellular proliferation—under other conditions it inhibits metabolism and destroys living tissues. Both clinical and pathological observations afford ample proof of both regenerative and degenerative tissue changes. *X*-ray degenerations vary from the acute degenerations associated with exudative inflammation to the chronic degenerations associated with an interstitial or productive inflammation leading to fibrosis and atrophy or a typical senile degeneration.

The variations in dosage which correspond to these various pathological tissue changes consist in alterations of quality and quantity or intensity and duration. Continuous *x*-rays are sedative, stimulant, irritant, or excharotic in proportion to an increase in intensity and duration. The higher the intensity the more acute the degenerations, and the resisting exudative inflammation. A lower degree of intensity and longer period of action, a chronic epithelial degeneration with a chronic exudative inflammation. The mildest intensity with the longest duration, the chronic productive inflammation or senile degeneration. The vascular changes consist in a vessel-stasis in the acute, and an arteriocapillary fibrosis in the chronic tissue degenerations. Inasmuch as these tissue changes do not appear to differ essentially from those pathological tissue changes of other types of irritants, their careful study might serve to simplify the subject of general pathology.

In normal metabolism we assume a balance between those processes which result in the storing up and the expenditure of energy, or anabolism and catabolism, or rest and work, characterized chiefly by an O_2 intake and CO_2 output. Both may be proportionately inhibited, sub-metabolism, or accelerated, hypermetabolism, without any disturbance of the normal work to rest ratio, and resulting in mere functional disturbance. The vascular change accompanying normal cellular phenomena is one of rhythmic capillary dilation and contraction, an intermittent action. Generation, and hence regeneration, must demand the maintenance of an equilibrium between capillary contraction and dilation, and hence between cellular work and rest. However obscure and complicated the nature of *x*-rays may be, we know that it is an energy, and as such is capable of doing a great deal of work upon living cells. The local exhibition of continuous *x*-rays create a persistent and uninterrupted tissue resistance, or work without rest. Beyond a certain degree of intensity and duration of action, both undeterminable factors, it exhausts tissue resistance, produces either a neuroparalytic or myoparalytic hyperemia with capillary stasis, from which they either recover or go on to chronic degenerations.

Almost all agents employed for stimulation act intermittently—massage, vibration, high frequency, the static spark, galvanism, faradism, high degree of heat, suction hyperemia, etc., and they all have one object in common, *i. e.* local active hyperemia. *x*-ray flashes create a local active hyperemia.

Inasmuch as a passive hyperemia with statis dominate continuous *x*-ray and other degenerations, it is apparent that to secure a regenerative action it would be necessary to induce an active hyperemia without stasis; to secure an increased arterial blood supply to promote cellular nutrition and to eliminate the products of perverted metabolism. But cellular regeneration, as we observe it in local inflammatory and ulcerative conditions, does not include the regeneration of degenerate cells. Exemplifying as it does the universal law of the survival of the fittest, it is manifestly a two-sided process, by virtue of which the unfittest cells undergo a more rapid disintegration and exfoliation, being forced, as it were, from their nutrient resources by a positive vital force, expressed through the appearance of more vigorous cells, the embryonic cells of the surviving fittest. The mere presence of degenerate cells in so-called local diseases must be indicative not only of a local vital depletion, but of some impairment of the general circulation, and consequently of general metabolism.

The keynote of *x*-ray therapy consists in the fact that the local hyperemic action depends for the most part upon the potent influence of radiant energy on general metabolism through the general circulation, and although we are able to obtain, by modifications of technique, a predominence of either a local or general action, under no conditions is it possible to absolutely separate the two, and no doubt the degree of success which may attend our efforts depends in a measure upon the adjustment of these two factors to the special requirements of each individual case.

To appreciate fully the influence of the general action of *x*-rays in local cellular degenerations, as in chronic pathological conditions of the eye, it is best to cast aside all histological and physiological specialization and to look upon the organ as merely one of many groupings of cells, of mesoblastic and epiblastic derivation, which constitute the general organism. As other cells, through the medium of the circulatory and nervous systems, they render support to and in turn receive support from the organism as a whole. And when we reflect upon the great disparity between what they give and what they must receive for their mere sustenance, we are then impressed with the vast importance of the study of the general metabolism with reference

to any chronic local condition. Owing to an extensive field of action and unique penetrability, the latter quality distinguishing radiant from other forms of energy, we would naturally expect it to possess a general influence quite beyond the range of other types of energy.

No stronger proof of a general action is needed than the sustaining power in such diseases of metabolism as leukemia, pseudoleukemia, pernicious anemia, and deeply seated cancer. A full appreciation of the general and local action of *x*-ray flashes can only be obtained by observations of the immediate and at times radical changes in the general circulation. Such observations not only reveal the peculiar therapeutic efficacy of *x*-ray energy, but also show why the resulting local tissue changes have a permanent tendency and are invariably accompanied by an improvement in mental and physical stability.

We have then to observe the action of intermittent *x*-rays upon the heart, arterial, venous, and lymphatic systems. When the cardiac sounds are weak, the action is to intensify them. With an accentuation of either the first or second sound, the result is one of equalization. With a high arterial tension and an accelerated pulse, the tension is reduced and the pulse retarded. With a high arterial tension and a retarded pulse, the tension is reduced and the pulse accelerated. With a low arterial tension and a retarded pulse, it raises the tension and accelerates the pulse. With a low arterial tension and an accelerated pulse it raises the tension and retards the pulse. Under all conditions an increase in the volume of the pulse is a notable feature. The superficial veins often show a moderate distention such as might appear after some sudden physical exertion. An increased capillary circulation of the skin is shown by the flushed appearance and mild diaphoresis. From clinical evidence, however, it would seem that a promotion of capillary circulation is quite universal, and this is the only explanation we can offer of the multitudinous changes which take place throughout the entire economy. There is presumably an action on the lymphatic system, as observed in effusions, exudations, and altered conditions of lymphatic glands. We have also observed an increase in respiratory movements. As a result, therefore, of equalizing the forces that control and dominate the circulation, an increased volume of arterial blood is distributed to the cells for nutrition and function.

General Action of X-ray Flashes.—The following indirect changes might be mentioned as a result of the promotion of the general capillary circulation. We sometimes observe an immediate loss of weight of from one to several ounces after each treatment. This probably means an increase in CO_2 and H_2O output. There is a gradual loss of weight of several pounds, following systematic treatment, after which there is a gradual gain which has varied from three to twenty pounds, and follows an improvement in the appetite. In obese subjects there is some loss of adipose tissue, with little or no loss in weight. The greatest increase in weight is seen in emaciated patients, and accompanies a general muscular development, particularly apparent in the face. The general appearance is one of greater compactness.

The urine at first may show an increase in the total daily output of urea, phosphates, and chlorides, also an increase in quantity. The blood may show an increase in both the red and white cells. When there is a disproportion between the two, as in leukemia, etc., the tendency is to increase the one and to diminish the other, as it were, to establish a normal balance.

There is evidence of a promotion of general glandular activity, both excretory and secretory. On the general nervous system the action is that of a tonic, and tends to restore a balance in nervous phenomena. Hence exaggerated reflexes are inhibited and sluggish reflexes stimulated. In certain cases a complete mental change has been the dominating feature, marked by an increase in will power and self-control and the same equalizing tendency in mental function when sluggish or exhilarated.

Local Action of X-ray Flashes.—In acute inflammatory processes the symptoms are intensified, with a tendency to run a more rapid course. A copious discharge of blood may follow the incision of a localized abscess previously radiated. There is an increased growth of the hair and nails. The hair after a time becomes darker, gray hair at times appearing black in streaks or iron-gray. There is an increase in sexual power, and evidence is accumulating that would make it appear that there is an increase in both potency and fertility. Absorption takes place in edemas, as in local venous obstruction or mitral insufficiency; also in effusions as seen in chronic sprains, hydrops articuli, etc. Fibrous tissue becomes more vascular, with a tendency to absorption, and if recent and poorly nourished, may break down completely. There is a softening of sclerosed arteries and veins, generally observed in the temporals. In chronic catarrhal conditions of mucous membranes, the tendency is at first to increase and later to inhibit secretion. There has been an improvement in hearing, and in one case a dilatation of the thickened Eustachian tube was demonstrated. There is a promotion of ovarian and uterine function. Menstruation was reestablished in one case, six months after the menopause. Two hundred flashes brought on menstruation when it had been suppressed for two years, one hour and a half after treatment. Cessation of leucorrhea has been noted in several cases, with no attempt at local treatment.

The Action of Flashes on the Eye.—We have observed the formation of new bloodvessels in fibrous tissue, such as remains after extensive corneal ulceration or in the fibrous thickening of the lens capsule following cataract extraction, with a tendency to contraction and absorption. Also an increase in the terminal twigs of the retinal artery, with an enlargement of the main trunks when contracted. The most notable results of the hyperemic action of *x*-rays in the eye are seen in conditions of chronic exudation, serous, fibrinous, and membranous, and, as one would naturally expect, they tend to respond in the order named. We have noticed an increase in the pupillary reaction to light, and in incipient tabes a moderate reaction has been obtained when there had previously been a reflex immobility. When the intraocular tension is + the tendency is to reduce it, and in degenerative conditions, with tension —, the result has been to increase it. A vascular keratitis with corneal ulceration or degeneration undoubtedly affords the best opportunity to study the local regenerative action of intermittent *x*-rays. The larger blood-vessels are seen to contract perhaps immediately after the first treatment. Shortly their identity will be more or less lost, and in their place there will appear a diffuse capillary congestion.

The absorption of exudates is shown both by a clearing of the cornea and an immediate improvement in visual acuity. Proliferation of corneal or connective tissue cells encroach upon the periphery of the area of necrosis. The result, therefore, is the substitution of a capillary hyperemia for a vessel stasis, or the conversion of a chronic into an acute process. An absorbent action of *x*-ray flashes is shown in corneal opacities, pupillary opacities, opacities of the vitreous, retinal, and choroidal exudates, and in subretinal effusion. A tonic action is seen in asthenopia, either with or without errors of refraction. Eye-strain, with the attending reflex nervous disturbance, has responded in numerous instances to a surprisingly limited number of flashes. By relieving the tension on the ciliary muscles they relax accommodation in cases of apparent myopia. In progressive degenerative conditions quite beyond the possibility of any improvement in vision they tend to fortify the more viable tissues and to facilitate the natural reparative processes.

Report of Cases.—About three hundred cases of extreme ocular conditions have been submitted to the intermittent *x*-ray treatment during the past two years, the vast majority of which were considered hopeless from the standpoint of the ophthalmologist. While in many cases only a slight visual improvement was apparent, there were comparatively few absolute failures, and the work, on the whole, has been most gratifying. The following are a few selected cases:

Case I.—Mrs. M.; atrophy of the optic nerve. Referred by Dr. Bowles, who furnished the following history: First seen November 23, 1906. She had been suffering for a few days with what was considered la grippe. Found slight febrile disturbance, more or less stupor, pains in head, heavily coated tongue, constipation, and somewhat incoherent. Mind acted sluggishly. Pupils dilated and vision reduced to fingers at about one foot. The ophthalmoscope showed some prominence about the optic disc, but otherwise negative. No specific history, although the characteristic treatment was persisted in until January, 1907. At this time V = 20/200.

On January 15 received hypodermic injections of strychnine, and continued the same daily until the 31st. There was slight improvement in vision, but it seemed to reach a point where it remained without change. To-day, April 18, 1908, V = 15/200. The projection is good. After the acute congestion of the brain had passed and with the gradual improvement in sight the optic atrophy showed. Neurotic. Muscles flabby, considerable obesity. Pulse sluggish, 74; blood-pressure 90 mm.

Received twenty-one treatments, three times weekly. The following records show the vision at each treatment:

18th — 10/100, 20th — 10/70 (2), 22d — 10/70, 24th — 10/40 (3), 27th — 10/50, 29th — 10/40 (2), May 4 — 10/40 (2), 6th — 10/40 (3), 8th — 10/30 (2), 11th, ditto, 13th — 10/30 (3), 15th — 10/30 (5), 18th, ditto, 20th — 10/30, 22d — 10/30, June 8 — 10/20 (1), 12th — 10/20 (2), 17th — 10/20 (5), July 8th — 10/20.

Under treatment the arterial tension rose from 90 mm. to 185 mm. and pulse from 74 to 80. Later the tension dropped to 145, the pulse remaining at 80. Mental and physical improvements were as decided as the visual. She lost adipose tissue, and the muscles became more firm. The patient was seen February 16, 1910, one year and seven months after discontinuing treatment. Her general condition had continued to improve. V. = 10/30; pulse 80. Blood pressure, 110 mm. When seen by Dr. Webster December, 1906, the patient could barely count fingers, and atrophy of the optic nerve had set in.

Examination by Dr. Webster February 20, 1910: O.D.V. = 17/200; O.S.V. = 20/70. Both fields complete—discs too white, arteries small, veins normal. This patient had applied to a blind home for admission, having been forced on account of failing vision to give up her profession, which was that of a music teacher. She has now taught music very successfully for over a year, and claims to have no difficulty in reading musical notes.

Case II.—Mr. H., age forty-eight; painter; detachment of retina. Gave history of a gradual loss of vision for past three years and more rapid loss for past six months. Had been under the care of specialists in Germany, Austria, Italy, and America. It is now difficult to go about. Examination by Dr. Webster February 4, 1908. O.D. — has detachment of the temporal half and lower part. O.D. V. = a little more than the perception of light. O.S. — has some choroidal trouble. O.S.V. = 20/100, with 2.75 D.

First treatment February 4. Skin cold and clammy, superficial venules congested. Shows effects of excessive beer drinking. Pulse, 95, volume small, irregular; sys. pressure, 135 mm.; obese., muscles flabby. After 250 *x*-ray flashes, pulse dropped to 80 and pressure to 120 mm. Immediate improvement in general circulation and vision. At second treatment pulse was 90 and more regular. Sys. pres., 95 mm. After treatment pulse 80 and still more regular. Systolic pressure raised to 125 mm. Cardiac sounds more evenly balanced. After the third treatment, Dr. Webster reported February 10: "The improvement has been very great in the one week since he was here. Ophtholmoscopic examination shows a clearing of the media and a contraction of the detachment of the right retina. In the left a choroidal trouble is much less. One week ago, O.D.V. = shadows; To-day, O.D.V. = 6/200; One week ago, O.S.V. = 20/100; To-day, O.S.V. = 20/30 every letter." Received seven more treatments, three times weekly, when Dr. Webster made a second report February 25: "O.D.V. = 20/200 which previously had a little more than the perception of light; O.S.V. = 20/30 which before treatment was 20/100 with — 2.75 D. Still some detachment in inferotemporal region."

The patient was satisfied with the improvement and moved to his former home in Texas, having previously taken up his trade.

Case III.—Mrs. I., age 46. Double atrophy. Referred by Dr. Ohly. Seen March 26th, 1908. Vision had been failing for three years. After consulting several specialists she was placed under mixed treatment, which she continued for three months from January to April, 1908. O.D.V. = 10/100; O.S.V. = 0. Possibly light perception at intervals. Both discs very pale, vessels small. Pulse 94, irregular, small volume, pressure 115 mm. Numerous small glands in posterior cervical chains. Two gummata on left ankle. Received three treatments weekly up to June 20. Both the pulse and blood pressure were lowered after the first treatment. During May the blood pressure rose to 160 mm. although the pulse remained at 80

or slightly above. Later the pressure came down to 110 mm. March 28, O.D.V. = 10/70; O.S.V. = Light perception; April 5, O.D.V. = 10/50; April 21, O.D.V. = 10/40 (two letters); May 2, O.D.V. = 10/40 (three letters); June 19, O.D.V. = 10/40 (every letter); O.S.V. = Perception of light. Treatment discontinued. Was last seen Oct. 24, seven months later. O.D.V. = 10/40; O.S.V. = Perception of light. She gained 8 lbs. in weight. Muscles previously flabby became more firm. Enlarged glands and gummata disappeared under *x*-ray treatment. Oct. 24, 1908, examination by Dr. Webster: O.D.V. = 20/70; O.S. = Light. Moved to distant State.

Case IV.—Miss D., age 16. Ulcerative keratitis and old corneal opacity. O.D.—Corneal capacity since she was two years of age; O.S. — Repeated attacks of corneal inflammation, almost yearly since the trouble in the right eye fourteen years ago. Examined by Dr. Webster September 3, 1908. O.D. — Old corneal opacities, one of them over the center of the pupil; O.D.V. = 4/200; O.S. — Ulcerative keratitis, quite vascular and extending from the temporal margin nearly over to the center of the cornea; O.S.V. = 20/70. The lids are inflamed and the eye, irritable, watery, and sensitive to light.

Patient poorly nourished and undersized. Poor circulation. Father gave specific history. After five treatments Dr. Webster made the following report, Sept. 13: "Inflammatory symptoms much improved. The ulcer nearly healed. Vascularity much diminished and the general redness, lachrymation, and photofobia are decidedly less. Vision of the right remains the same. The left has improved from 20/70 + to 20/50 +. After six more treatments, Dr. Webster reported Sept. 29 as follows: O.D.V. which was 4/200 is now 16/200 (old opacity); O.S.V.—the same. The keratitis is gone, the vascular redness having entirely disappeared. Nov. 9: O.D.V. = 20/100; O.S.V. = 20/30 with astigmatism corrected. Patient continued to receive treatment irregularly for more than a year and while no further visual improvement was obtained there was a gradual improvement in her general condition, marked by a better circulation, increase in muscular strength and endurance. She has had no further attacks since her first treatment. She gave up her position in a blind institute and is now able to use her eyes for her self-support, which prior to treatment was an impossibility.

Case V.—Mr. D., age 55. Optic atrophy. First seen June 5, 1908. Suddenly lost all sight in left eye twenty-four years previously. Specific infection at twenty-five years of age. Otherwise negative. During the past year the sight of the right eye had been gradually failing. Had been under the care of several specialists. Had taken 180 grs. of K. I. per diem, for the past year. Laterly had begun injections of strychnine but with persistent failure in vision. Poorly nourished, muscles flabby, neurotic. P. 80, Systolic pressure 250 mm. Discs showed atrophy. Marked contraction of the right visual field. O.S.V. = 0; O.D.V. = 1/2/200. Received in all ten treatments, once weekly. The record of vision was as follows: O.D.V. — 1/2/200 — 2/200 — 1/2/200 — 5/200 — 10/200 — 10/70 — 10/50 — 10/40 — 10/30 — 10/20 — 10/15. Sept. 8, sat up till 2 o'clock in the morning to read a book of fine print. He awoke next morning in complete darkness. Sept. 9, examined by Dr. Webster. Diagnosis: Hemorrhage in vitreous. Vision reduced to light. Weekly treatments continued. October 8: V. — 1/200; November 27: V — 3/200. Later vision came up to 7/200 and the ophthalmoscope showed the red reflex in limited area. Patient unable to come to town for further treatment.

Case V.—Miss P., age 24. Central corneal opacities and pupillary membrances following needling operations for congenital contaract. Referred by Dr. Webster, January 11, 1908, with the following note: "Miss P. was operated upon by me for congenital cataract when eight years old. Both eyes were operated upon by needling and there were four or five operations in all. She now has central opacities of both corneæ and some pupillary membrane, reducing her vision to O.D.V. — 20/100; O.S.V. — 20/200. I would suggest that you first try to improve the sight of the poorer (left) eye. Treatment 100 Fl. High tube. Distance 8 inches. Right covered with lead foil. Both eyes responded to the first treatment. Before first treatment O.D.V. = 10/50; after 10/40. Before treatment: O.S.V. = 10/70; after 10/50. Before second treatment: O.D.V. = 10/30; after 10/30; O.S.V. = 10/50; after 10/40. After fourth treatment: O.D.V. = 10/20; O.S.V. = 10/40. The patient was not seen again for three months and during that time more than held the improvement. April 22: O.D.V. = 10/20 full; O.S.V. = 10/40. Received seven more treatments. May 4: O.D.V. = 10/15; O.S.V. = 10/20. Nearly six months later vision remained the same. Before treatment pulse was small, 95 and irregular. Poorly nourished, skin cold and clammy. Blood pressure 70. Effect of treatment: pulse 80, blood pressure 85. Physical and mental improvement. Previously helpless, she was making her own living when last seen, and claimed to be unconscious of any visual weakness.

Case VII.—Miss H., age 28. Double atrophy. Seen June 19, 1908. Twelve years ago she suffered with severe headaches at which time she had done an inordinate amount of reading, mostly in a recumbent posture. Blindness came on gradually. She had not made out objects for twelve years. No specific history. O.D.V. = Perception of light; O.S.V. = 0. Slight external strabismus of left eye and double rotary nystagmus. Under weight. Poor general circulation, neurotic. Pulse rapid, volume small. Low blood pressure. Received treatments, twice weekly for six months. June 30: O.D.V. = shadows; July 7: O.D. — perceived letters on Snellen's card, but could not distinguish them; August 7, read the top letter at 4 inches. This was the first letter she had seen for twelve years, and was slow in naming it, although she had traced it with her finger very readily. August 11: O.S.V. = Perception of light; November 27: O.D.V. = 1/200; December 2: 3/200. About a year later patient returned for further treatment. Vision remained about the same. The strabismus was less marked. Nystagmus decidedly less. Improvement in general circulation. No further improvement in vision.

Case VIII.—Mr. W., age 75. Double atrophy. Referred by Dr. Webster, May 29th, 1909, with the following history and examination: He has been unable to see when it becomes dark for six or eight years. Left eye never saw well. Had grippe several times and malaria several years ago. Had lead poisoning 25 years ago. He ate it, the lead having

been ground in the flour. Atrophy of both optic discs, with some atrophic excavation. Visual fields very defective. Lower part of right and upper part of left gone. Also nasal part of left absent and both contracted in all directions. Right eye also has incipient cataract. Anterior chambers rather shallow, tension plus? Pupils respond to light and accommodation sluggishly. He has exhausted K. I. mercury, strychnine, etc. I found the pulse irregular and of small volume, rather rapid. Blood pressure 110 mm., low for his age. Physical strength impaired and mentally irritable. Reflexes sluggish. Abdomen distended. Diminished respiratory capacity. After first treatment pulse came to 72 from 80, blood pressure from 110 mm. to 125 mm. More color and warmth to previously cold and pale skin. O.D.V. — from 10/40 to 10/40 full. O.S.V. — from 0 to light. Received six treatments and was then examined by Dr. Webster, who reported as follows: June 12, 1909: O.D.V. = 10/30; O.S.V. = Quick perception of light. The field of vision of O. D. is certainly appreciably larger. Continued treatments once a week. July 21: O.D.V. = 10/15; August 1: O.D.V. = 10/15, in spite of illness and no treatment since previous record. Being satisfied with improvement, as he is able to read and write, he discontinued treatment. Physically and mentally there was a decided improvement. In appearance and action he seemed younger. He mentioned a rapid growth of hair and beard. He felt stronger than he had for several years and had noticed a better general circulation, especially during the winter months. Pulse slower, more regular, more volume. Blood pressure higher and more stable. Temporals and radials softer.

Case IX.—Mr. M., age 26. Leucoma adherens. The Fourth of July, 13 years ago, an explosion of fireworks struck the left eye, leaving him with very little vision. Dr. Webster made an examination Sept. 23, 1908, which was as follows: "The large leucoma adherens at the inferotemporal portion of the cornea and the aphasia of the eye are sufficient to explain the reduction of its vision to ability to see objects, but he could not count fingers. I could not see the fundus, but the ophthalmometer shows that the irregular astigmatism is tremendous. The retina appears normal." O.S.V. = objects. Pulse small and irregular. Low blood pressure. Skin lacks warmth. Muscles flabby. Excessive adipose tissue. Received six treatments.

Dr. Webster's second examination, October 10: "There can be no doubt of the improvement of left eye. O. S. V. = 20/200 with + 12 D. He was carefully tested with + glasses and cylindrics at the first visit without improvement." Did not appear for further treatment.

Case X.—Mr. B., age 41. Detachment of retina. Referred by Dr. Franz Torek. Thirty-six years ago fell down the stairs striking his eye against a drawer. Totally blind in left eye for 20 years. Limited vision in right for 17 years. Dr. Webster's examination on Feb. 15, 1908: "O.D. — detachment of most of the retina; O.D.V. = 10/200; O.S. — mature cataract and probably total detachment."

Appeared for treatment March 17. Poorly nourished. Pulse 100, irregular. Systolic pressure, 125 mm. Body covered with small lipomata; one large one which covered the left eye removed by Dr. Torek. After first treatment, pulse, 90; systolic pressure, 115 mm. Immediate improvement in vision.

Second treatment: O.D.V. = 10/100. O.S.V. = Perception of light. Received 27 treatments. O.D. continued to improve, but no further change in O. S. Treatments, 3 times weekly.

March 21, O. D. V., 10/70; 22d, 10/50; 25th, 10/40; May 8, 10/30; July 11, 10/20 + Read J, No. 1.

Dr. Webster's report, Sept. 8: "The detachment is considerably less. This is accomplishing a good deal when we consider that in ordinary conditions the tendency of detachment is to become worse."

In the course of treatment the pulse went from 100 to 64, and later to 80. Sys. pres. from 125 mm. to 85 mm., later to 175 mm., finally to 100 mm. Improvement in general circulation and general physical condition.

Last seen Feb. 16, 1910, one year and five months after last treatment. General improvement more marked. Pulse 80. Systolic pressure 115 mm. Could read and write without difficulty and was unconscious of any impairment of vision. Read J, No. 1. Also seen by Dr. Webster the same date. O.D.V. = 20/100; gl., 20/40, reads every letter with — 3 D. No glass had helped him before treatment. Still some detachment in lower part not interfering with vision.

Case XI.—Miss H., age 49. Leucoma adherens —artificial pupils. Rendered blind when 13 years of age by some unknown corrosive. Was totally blind up to her nineteenth year, when an operation restored some sight, which she lost completely at her forty-second year.

In February, 1908, was operated upon by Dr. Pagenstecher, of Wiesbaden, where she remained under treatment for 15 weeks. Before she left Europe she was able to read her own letters. Later, however, her vision began to fail again and she had very little by the time she reached New York.

Examined by Dr. Webster, October 8, 1908: "Both eyes have leucoma adherens, very extensive, and that of the left largely degenerated. The right has had a cataract extracted and has an artificial pupil behind the semi-opaque cornea at the nasal side. The left has an artificial pupil behind the semi-opaque cornea on the temporal side. The fundus cannot be examined, but a dim reflex can be seen through the artificial pupils. R.V. = 1/200; L. = 4/200, not improved by glasses."

Treated daily for 17 successive days. Immediately after the first treatment the cornea appeared more transparent and the fundus showed more reflex. R.V. = 3/200; L. = 6/200. After the eighth treatment she came alone for treatment, and thereafter went about the city in which she was a stranger without any difficulty.

Oct. 15: R.V. = 14/200; L. = 10/100. Oct. 21 made out several words in J. No. 7 with her + lenses. She returned to her home in the West and we have heard from her from time to time. She reported still further improvement and is able to read and write, as her letters bear witness.

Case XII.—Mrs. S., age 37. Double atrophy. Vision had been failing for about two years, in spite of persistent treatment with routine measures. Seen by Dr. Webster, June 14, 1908. Diagnosis: Atrophy of both optic nerves, probably from old "blood-poisoning," as she has had two miscarriages and no living children. She has only perception of light in both eyes. Began treatment June 17. Pulse, 120. Systolic pressure, 170 mm. After first treatment: P., 90; systolic pressure, 130 mm., with immediate improvement in vision.

June 24, third treatment: Pulse, 88; systolic pressure, 120 mm.; V. = 1/200. Received treatments twice weekly for four months; after that very irregularly, with intervals of a month. Dr. Webster reported Oct. 22: "There can be no doubt of Mrs. S.'s improvement. She called G O at 5 ft., but traced the letter Z with her finger and called it Z correctly." Last examination Feb. 23, 1910 (Webster). "Mrs. S. picks out some of the playing cards correctly. She also names the letters in Snellen No. 100 correctly, and one letter in No. 70 at about one foot. When I first saw her on June 14, 1908, she had only perception of light. She has white atrophy of both optic nerves, and it is good to find her vision better instead of worse after an interval of more than a year."

This patient was exceedingly obese and neurotic; while under treatment she received several nervous shocks, after which there would be a rise in blood-pressure and acceleration of the pulse with diminution of vision. Treatments always lowered the pulse and pressure; she would become more calm and her vision would then be restored. There has been a decided general improvement, especially in her nervous condition.

Case XIII.—Dr. E., age 63. Corneal ulceration and opacity (carbolic acid burn). Referred by Dr. Webster, December 15, 1908. Ten weeks previously several drops of carbolic acid got in his right eye. Had spent one month in a dark room, under the influence of morphine for severe pain, using boric acid continuously. Pupil kept dilated for iritis. Later had used dionin (5 per cent. solution). For one month could not distinguish light from dark. Not much improvement during past few weeks. Was not able to use the good eye. Examination: Pupil responds slowly to light. Cornea more or less opaque and vascular and the conjunctiva drawn over the lower border. V. = 4/200; pulse, 84; systolic pressure, 165 mm. Immediately after first treatment, pulse 78, systolic pressure, 145 mm. Improvement in general color. Intense lachrymation, cornea clearer. Large vessels contracted. Redness of brighter color and more diffuse. He could open his eye wider, and said things looked clearer. V. = 8/200. On the second day before treatment, V. = 10/200; after treatment — 15/200. Cornea clearer, redness less. On the third day, V. before treatment was 10/100; after, no change. Was able to open eye and had read a newspaper with no discomfort. Business compelled him to leave the city, and hence to abandon treatment after only three applications. Received word January 7: "I found on my return I could use the eye to do many things I could not do before, and since my return there seems to have been a steady improvemnt, so that I am attending regularly to my practice with very little inconvenience." Patient had come to New York expecting to have the eye enucleated to enable him to use the left eye with comfort.

Case XIV.—Mrs. H., age 62. Immature cataract; iridochoroiditis; double iridectomy. Without perception of light in left eye, and with very little vision in the right for nine years. Dr. Webster's examination June 14, 1908: "Mrs. H. had iridectomy on both eyes eight years ago for iritis, or more probably for iridochoroiditis. There is immature cataract of both eyes besides the old iridochoroiditis. The tension is — in both. The field of perception is blunted on the nasal side of the right. In the left it is very small, beginning in the center and extending upward. Impossible to see fundus. O.D.V. = 2/200; O.S.V. = 0." General condition, muscles soft, skin flabby and colorless, excessive adipose tissue, reflexes sluggish. Very much below par, physically and mentally. Pulse, 88; systolic pressure, 190 mm. After first treatment, pulse 80, systolic pressure, 145 mm. Skin had more color, eyes appeared clearer, and she felt more comfortable. June 16: O.D.V. = 4/200; O.S.V. = first perception of light for nine years. Pulse, 76; systolic pressure, 140 mm. Received eight treatments. Examined by Dr. Webster June 21. O.D.V. = 8/200; O.S.V. — sees hand but cannot count fingers. July 3: O.D.V. = 10/200. No further treatment. Last seen October 24, 1908; no change in vision; improvement in general health; pulse, 80; systolic pressure, 165.

Conclusions.—1. In the ophthalmic application of intermittent *x*-rays a failure to obtain a maximum therapeutic effect is frequently attributable to two factors: Either to an incomplete reaction from a faulty technique or inefficient apparatus or to local hyperstimulation by continuing treatment when a satisfactory reaction has been obtained.

2. Inasmuch as both functional and physical improvement in ocular derangements always follow a readjustment of the general circulation and changes in general metabolism, the peculiar qualities of radiant energy on metabolism would appear to emphasize a causal relation between the two.

3. In an effort to find manifestations of unbalanced metabolism in patients with chronic ocular conditions, we have been impressed with what appears to be significant features. Bishop, in his observations in circulatory derangements, found two distinct types of blood pressure, the persistent high and the persistent low. In our cases we have found the same, and in addition a variable type in which there is a tendency of one type to pass to the other. Some patients have a pulse habitually fast, others correspondingly slow. Some are over weight, others under weight. Respiratory movements are accelerated in some and retarded in others. Mentally some show hypercerebration, others subcerebration. The nerve reflexes are retarded or exaggerated. The glandular organs show hyperactivity or subactivity. In muscular tissues we find soft muscles with a tendency to obesity, and flabby muscles with excessive leanness.

In the extreme types we continually find a contraction of the thoracic cavity and a corresponding relaxation of the abdominal cavity, associated with which there is a tendency to intestinal functional disturbance and toxemia. In brief, a condition of lowered general vitality from submetabolism or hypermetabolism. If such evidences of perverted metabolism have any influence in chronic degenerative conditions of the eye, the same causal relations must exist between those same metabolic changes and degenerative conditions of other tissues.

4. If radiant energy has a favorable influence on extreme ocular conditions when other means have failed, may we not expect that it would have a more potent preventive action if resorted to in incipient stages?

120 East Thirty-fourth Street.

Exophthalmic Goiter in a Child.—Pritchard reports the case of a boy of eight years who was mentally backward. His thyroid was enlarged, there was slight exophthalmos. Graefe's and Mobius' signs were present.—*Proceedings of the Royal Society of Medicine.*

THE SIGNIFICANCE OF LEUCORRHEA.*

By AUGUSTIN H. GOELET, M.D.,

NEW YORK.

PROFESSOR OF DISEASES OF WOMEN, NEW YORK SCHOOL OF CLINICAL MEDICINE; GYNECOLOGIST TO THE WEST SIDE GERMAN DISPENSARY AND HOSPITAL, ETC.

THERE is little herein detailed that is not already known, though it may be often disregarded, many times perhaps because the average practitioner is not properly equipped for dealing with such cases. Yet there is no more serious error than to dismiss a patient having a vaginal discharge, without carefully investigating its true character, and prescribing only a wash or injection to be used unintelligently and indifferently, because the patient is not made to appreciate its true significance. If failure to afford relief was the only penalty, such error might be pardoned, but often failure to recognize and promptly combat the condition that gives rise to a vaginal discharge leads to serious consequences, involving the life or future health and happiness of the patient.

It is an indisputable fact that the lives of many women have been jeopardized or their health and happiness completely wrecked because of neglect, in the early stage, of some infection which would have been evident to an acute observer and the progress of which could have been arrested in this stage. In justice to the physician it must be said that the patient or her mother is often to blame for not calling attention to a discharge that unfortunately is too often regarded only in the light of an inconvenience. On the other hand, she has not been taught to appreciate the full significance of a vaginal discharge, and has not had pointed out to her the possibilities that may arise from neglecting it. Hence it is clearly the duty of the physician to educate his patients to a proper appreciation of this one symptom (leucorrhea) in particular. True some leucorrheas are innocuous, but it is the physician's privilege to decide this, and he should equip himself to make his decision reliable.

Let us see what may be the significance of a vaginal discharge at different stages of woman's life, viz., *in childhood before puberty; in young women before marriage; in married women,* and in *women past the menopause.*

In Childhood before Puberty.—At this period a discharge may denote an infective vulvovaginitis that may originate in many ways unsuspected by the mother. I recall a case that came under my observation where the infection had been contracted from another child whose nurse carelessly dried the genitals, after bathing, with a towel that had been used by one of her older brothers who had used it and thrown it down carelessly among the other soiled clothes. Examination of the discharge in this case revealed the presence of gonococci in abundance. Unfortunately its character had not been ascertained sufficiently early to prevent extention of the disease to the uterus.

I have observed septic endometritis with involvement of the adnexa in young women, virgins, where there was a history of purulent discharge from the genitals during childhood that had not been given proper attention at that time and where no other cause could be assigned for the condition.

A less virulent form of infection may arise from contact of unclean hands with the genitals; either those of the child herself or those of her playmates; for children will indulge in play of this kind, sometimes innocently and sometimes by example of their nurse. I am inclined to believe from observation that some precocious children derive pleasurable sensation from such practice which may have had its origin in the use of strong, irritating soap. Mothers should be instructed that soap is not always essential to secure cleanliness of the genitals of children, and that irritating soaps should be avoided.

In this connection I recall a very interesting case; a beautiful child of five was brought to me by the mother who observed a discharge from the vulva that proved to be a simple vulvovaginitis. It was subdued, but there was prompt recurrence upon suspending treatment. The mother was directed to watch the child, particularly after she was put to bed at night and it was soon discovered that when pretending to be asleep she would rub the genitals. Close observation gave evidence of intentional titillation. The practice was corrected and prompt cure of the condition resulted. The origin of the practice in this case could not be traced, but the discharge was kept up by excitement of the genitals.

Vaginal discharge in children may also arise from the presence of foreign bodies, as bits of coal. In one case the vagina was found filled with bits of coal which the child declared had been introduced by a playmate. In another case several shoe buttons were found, and in another a hairpin.

A vulvovaginitis may arise, as every physician knows, from the irritation produced by the presence of worms in the rectum or from their entrance into the vagina. A vulvitis may also result from uncleanliness due to decomposed smegma, sweat or urine, particularly in warm weather, and from hyperacidity. It must be remembered also that children of strumous diathesis and those who are poorly nourished and who live in unhealthy surroundings are prone to have discharges from mucous surfaces that are sometimes communicable.

But by far the most frequent cause of vulvovaginitis in children is gonorrheal infection, not necessarily the result of violation but most often from unclean habits. This furnishes a strong plea for careful microscopic examination of the discharge from the genitals of all female children, whether it appears to be suspicious or not.

In Young Women before Marriage.—These are the cases most often neglected, owing to false modesty on the part of both the mother and the daughter, shared only too often by the family physician. It has frequently occurred that the unsuspecting mother and physician have permitted the neglect of a vulvovaginitis of gonorrheal origin because a proper examination was not insisted on, depending upon external irrigation or imperfect vaginal irrigation by the patient to cure the discharge, the character of which was unknown, even to the physician. The physician, like the detective, some of whose methods he might well imitate, should never think any female patient with a vaginal discharge above suspicion; though he need not express this opinion or show it in any way by his conduct. When his suspicion has been confirmed he need not even then feel obliged to reveal it, if he can without doing so, convey a proper appreciation of the necessity for the vigorous measures required to combat the disease successfully. When consent to examination is not given, the stains on the linen may,

*Read by invitation at the twelfth annual session of the Tri-State Medical Association of the Carolinas and Virginia held at Richmond, February 15 to 17, 1910, and before the Tri-professional Medical Society, New York, March 15, 1910.

with the connivance of the mother, be obtained for examination, and if that reveals the necessity for local examination and treatment it can be put so strongly to the patient that she will fear further refusal.

The writer was once so unfortunate as to get an infection of the finger by making a digital examination of a supposed virgin who came to him for relief of dysmenorrhea. Subsequent inspection revealed an active specific vulvitis and vaginitis, the discharge under the microscope showing gonococci and streptococci in abundance. This patient did not complain of any discharge, in fact denied its existence. I am satisfied she was ignorant of the nature of the disease, but this lesson teaches that we cannot be too particular in our investigation and in the examination of young women who come or are brought to us for treatment; for our own sake, as well as theirs.

The discharge in young women is sometimes found to be a continuation of a vulvovaginitis from childhood that has been neglected. A young society lady was brought to me by her married sister who stated she had a discharge from early childhood and that she had received treatment from the family physician from time to time. He had made an examination and had prescribed washes at different times, but as no permanent benefit resulted it was concluded that the discharge was chronic and for a long time it had been neglected. Since puberty nothing had been done for it, but finally it had become unbearable. Unfortunately the uterus and adnexa were involved when she was brought to me.

A specific vaginal discharge may arise from other sources than direct infection from the male, as for instance from unclean towels that have been used by other members of the family or female companions, unclean bed linen and infected clothing, under garments, and bathing suits. The nozzle of the syringe is a frequent source of infection, for no pains is ever taken to keep it clean and the necessity for having it perfectly clean before using it is rarely thought of. Contact with unclean toilet seats in public places is by no means so infrequent a source of infection as is supposed, and the physician should caution his patients not to sit down in such places. The custom of the French, who stand or stoop over an opening in the floor, might well be imitated in this country.

Though infection is frequently the cause of vaginal discharge in young women, even those in the higher walks of life, it must not be inferred that leucorrhea may not originate from other sources, and may be of minor significance, yet have an important bearing on the future well being of the patient. For instance masturbation is a frequent cause of leucorrhea as well as sexual excitement from intimate association of the sexes, even when it does not overstep the customary limitations of polite society. It may result also from a catarrhal endometritis, or uterine displacements, or from conditions that cause dysmenorrhea; constipation or any other condition that produces pelvic congestion, pelvic tumors, etc. Leucorrhea is also observed in anemic subjects and may occur also as the result of hyperacidity. Whatever its source the physician should always inform himself of its character and endeavor to correct it. But from what has been said it can plainly be seen that leucorrhea is frequently viewed with indifference, and the source of possible infection is often diregarded.

In Married Women.—Unfortunately women are too often led to believe that leucorrhea is usual after marriage, that it has no special significance, and therefore is to be disregarded or regarded only in the light of a necessary inconvenience. Though it may sometimes have no special significance as a rule it should always be considered abnormal when it is constant or when it recurs repeatedly and should then receive the prompt attention of the physician. It may constitute only an increase of the normal secretion, yet may be evidence of an abnormal condition that should be corrected; and on the other hand, it may be the result of some suppurative process due to infection of a serious character. It is therefore clearly the duty of the physician to make a careful investigation in every case when a vaginal discharge is discovered or is complained of by the patient and to ascertain its character and source. It is not sufficient to know that the discharge contains pus and bacteria, but the kind of bacteria is important, and it is also important to determine whether it proceeds from the urethra, or the cervix alone, or from the cavity of the uterus. The physician who practises gynecology without employing the microscope and other known means of facilitating diagnosis in these cases is doing blind work which is oftentimes worse than useless, and he is equally as culpable as he who is satisfied to prescribe a vaginal wash for leucorrhea.

Vaginal discharge in recently married women always demands prompt attention, for unfortunately it is not unusual for young men to marry while they still have a gleet or when they have not been pronounced cured of a gonorrhea. It must be borne in mind that absence of discharge is not evidence of cure, for this disease often lurks in the prostate long after all visible evidence of discharge has disappeared. I once did an abdominal section on the wife of a physician whose pelvic organs presented unmistakable evidence of gonorrheal invasion. After seeing the condition the doctor asked to have his prostate examined, stating that he had contracted the disease sixteen years before marriage and believed himself cured. Examination of his prostatic secretion revealed gonococci.

It is the duty of the physician to educate his patients to a proper appreciation of the danger to the young wife who marries a man that has previously had gonorrhea. I feel so strongly upon this point that I think an enforced examination and a clean bill of health from a competent specialist should be demanded before a man is permitted to marry. If fathers and mothers of young women could be made to appreciate its importance it would not be long before such a demand would become a custom; then the work of the gynecologist would be greatly curtailed.

It is equally important that the man who contracts gonorrhea after marriage should not cohabit until he is pronounced cured. Unfortunately, every man is not properly informed upon this subject, and he has but a vague conception of its importance. It is quite true that this disease may be contracted by the wife from other sources than her husband. I once discovered it in a young wife, whose chastity could not be questioned, and the husband denied ever having had it. I was interested to ascertain its origin and was persistent in my investigation to that end. Eventually it was learned that their maid had the disease and had used the fountain syringe of her mistress that had been left carelessly hanging in the bathroom.

It is most unfortunate that the belief is so uni-

versal, not only with the public but also with many physicians, that gonorrheal infection in women must always manifest itself by a burning upon urination and a profuse purulent discharge; in fact, that there must always be a primary urethritis and vaginitis. Some authorities contend that the urethra is the most frequent location of the primary infection in women. My experience convinces me that the cervix is the most frequent seat of infection and that it often occurs without primary urethral infection. The vulva may be the seat of primary infection also, but primary gonorrheal vaginitis is rare.

Gonorrheal infection of the cervix is very much more frequent than is generally realized, even by the physician, and frequently is unsuspected because there is not always a profuse or suspicious discharge. And these are the most dangerous cases because they are not suspected. The infection is lurking in the glands of the cervix and is not manifest even in the discharge in some cases except under some unusual excitement or irritation that causes the glands to throw off the secretion in unusual quantity. But it is always possible to make a correct diagnosis in such cases by examination of the secretion after intentionally provoked irritation.

There are other forms of infection encountered in women that are only a little less harmful; viz., the streptococcus and staphylococcus, either alone or together. Both may be transmitted to the male and produce an inflammation quite as intractable sometimes as that caused by the gonococcus. It is this form of infection lurking in the generative tract of women that gives rise to inflammatory conditions following the introduction of instruments into the uterus, and that sometimes follows abortion and labor. Hence the importance of detecting the presence of bacteria in the leucorrheal discharge. These microorganisms make their way along the course of the lymphatics of the broad ligaments by absorption from the uterus, producing, under conditions favorable for their development, cellulitis and peritonitis and sometimes abscess in the pelvis.

The woman who harbors these bacteria in her genital tract is living over a veritable volcano that is ready to burst forth at any time under favorable conditions, supplied by some slight traumatism or act of imprudence, like exposure to cold. Fortunately, these microorganisms manifest their presence by the so-called leucorrhea, because they provoke irritation that causes increase of secretion, which is a warning; but if this warning is disregarded the result must be anticipated.

The manner of their introduction into the vagina is not easily determined, but probably the most frequent means of transmission is by the nozzle of the syringe, which is never clean. It is kicked around the floor, and it would seem that every effort is made to insure its infection. Even the inside of the fountain syringe is a fruitful source of infection, for the rectal nozzle, after it has been used, is invariably inserted into the mouth of the bag, as is also the vaginal nozzle.

Women who are guilty of these unclean habits are really not to blame, for they have not been warned of their danger. A woman who was well enough informed to be suspicious of any unusual leucorrheal discharge, once consulted me for a very profuse purulent discharge which she thought might have been contracted from the man with whom she was living. It proved to be a mixed infection of the streptococcus and staphylococcus, that had invaded the uterus. Her suspicions were allayed, and I endeavored to trace the source of infection. She admitted being careless with the nozzle of her syringe, but had no servant. She had, however, two pet dogs that often played with the nozzle of the syringe as it hung in the bathroom.

The colon bacillus and the tubercle bacillus, as well as the various saprophytes, are also found in the vaginal discharge sometimes, and their source and significance should be ascertained when possible. There may be a rectovaginal or rectouterine fistula, or the discharge from an anal fistula may find its way, first to the vulva, then into the vagina. A patient once came to me complaining of what she designated a profuse, offensive leucorrhea, the source of which proved to be an anal fistula, and the vagina was fortunately not involved. The source of a vaginal discharge may be cancer of the endometrium or of the cervix, or of the body of the uterus, and the discharge would also be designated leucorrhea by the patient.

A married lady, who consulted me for hemorrhage from the uterus that proved to proceed from cancer of the cervix, admitted that she had been having a rather offensive leucorrhea for several months or a year before bleeding occurred, but she paid no attention to it because she was afraid if she consulted a physician he would find something that required treatment.

Anything that causes congestion of the pelvic organs may produce a leucorrhea; for instance, constipation, an inactive and congested liver, intestinal indigestion, tight lacing, prolapse of the kidneys, by interfering with the return circulation through the ovarian veins, unusual sexual excitement, particularly when it is not relieved, sexual excesses, efforts to prevent conception, etc. Such a state of congestion, if not corrected, leads to catarrhal inflammation and makes the genital tract receptive of infection that would be resisted if a normal state prevailed. In other words, a congested mucous membrane is a fertile field for the development of pathogenic bacteria.

It is well known that a woman is more readily infected after an abortion or labor, because the tissues are less resistive than before. For instance, a woman married to a man with chronic prostatitis may resist infection before the first pregnancy, but will become promptly infected after.

A frequent cause of leucorrhea also is the use of irritating substances in the vaginal douche. This is particularly noticeable when the vaginal mucous membrane is sensitive, as it is in some women. I have known the use of bichloride solution and soap also to produce an annoying leucorrhea that promptly subsided upon discontinuing the douches. Hence, prolonged and too vigorous efforts to cure it may cause continuance of a leucorrheal discharge.

It is very unfortunate that the term leucorrhea is used so indiscriminately to designate any and all forms of discharge from the female genitalia. It is so frequently given as a symptom by the patient who consults the physician that it has come to be regarded as natural, and its actual character is seldom noted. All women, especially married women, have a perceptible secretion at times, or rather a moisture, about the vulvar orifice. This is not significant and requires no attention. But if an apparently normal secretion is persistent or sufficiently profuse to produce inconvenience it would be safer for the woman to consult a physician and to let him decide if it requires attention.

In Women Past the Menopause.—At no period of

a woman's life is investigation of the vaginal discharge more important than after the menopause. The popular belief that women past the menopause are or should be exempt from disease of the generative apparatus is very unfortunate, because it often leads to neglect of conditions that are serious. It is strange, but women at this stage of life frequently deny the existence of a discharge that is actually causing annoyance, especially women who have never been married or have never had children. Conditions that may cause a vaginal discharge are by no means limited to women who have had children, but are also encountered in unmarried women past the menopause. This is particularly true of senile endometritis, which is found not infrequently in unmarried women after the change of life.

Leucorrhea at this period may be evidence of cancer of the uterus or a senile endometritis and vaginitis, or it may be caused also by fistula, fibroid tumors, and other tumors of the pelvis, and the same inflammation that occurs at an earlier age. Infection of the genital tract at this period is rare, but it does occur undoubtedly. Diabetes gives rise to a most annoying discharge and a vulvitis at this period, and sometimes constipation and hyperacidity will also produce leucorrhea. Uterine displacements at this period are generally found associated with senile endometritis, but do not act as an independent cause of the discharge.

But by far the most frequent causes of discharge in women at this period are senile endometritis and cancer of the uterus; both of which are of great importance. The one, senile endometritis, because it leads to constant ill health, or chronic invalidism and premature aging; and the other, cancer, because it endangers the life of the patient, and if it progresses too far before it is discovered, means death within a very short time.

The constitutional symptoms of these two conditions, as well as their local manifestations, are sufficiently similar to cause the one to be mistaken for the other by the casual observer, who has had a limited experience with such conditions. They both give rise to a discharge that is sometimes offensive and sometimes tinged with blood, and there may be occasional bleeding that might be regarded as one of the vagaries of change of life.

Enough has been said to show the necessity of careful investigation of this symptom (leucorrhea) and it is to be hoped that the family physician, who is usually the first to discover it or learn of its existence, will be aroused to an appreciation of its very great importance and insist upon an investigation to determine its character and source whenever it is encountered.

The significance of the altered vaginal secretion during pregnancy has not been gone into, not because it is any less important, but because of insufficient time and space in this paper. On the contrary the abnormal secretion of the pregnant state is of such importance that it should be taken up separately, and I sincerely hope to see the subject dealt with by some competent obstetrician.

2030 Broadway.

Typhoid Bacilli in Butter.—The vitality of the typhoid bacilli has been investigated both in butter and in milk. On the 151st day after the manufacture of butter from milk infected with typhoid germs living colonies of these bacilli developed on plates that were made from the butter, proving that these bacilli retain their vitality and are ready to multiply whenever opportunity presents for 151 days.—*Report of the U. S. Bureau of Annual Industry.*

DIAGNOSIS OF LESIONS OF THE ABDOMINAL VISCERA, WITH ESPECIAL REFERENCE TO THEIR FUNCTIONAL INTEGRITY.

By HERBERT SWIFT CARTER, M.D.,

NEW YORK.

ATTENDING PHYSICIAN, LINCOLN HOSPITAL, CHIEF OF MEDICAL CLINIC, THE PRESBYTERIAN HOSPITAL DISPENSARY.

During the past few years a large amount has been added to our knowledge of the diseases of the abdominal organs, and regions long thought to be inaccessible and conditions thought impossible of any but a tentative diagnosis, have, by the aid of chemical and bacteriological methods, been brought easily within the reach of the clinician, so that now with care and patience one may safely make diagnoses, which would but a short time ago have seemed, to say the least, venturesome. To accomplish this one must have, of course, a certain amount of laboratory knowledge or assistance, but for the most part it need be but of the less complicated sort and quite capable of being put through in a short time, leaving the more complicated measures for the expert chemist or at least for one quite familiar with the more recent methods of chemical analysis. Let it be definitely understood at the start that these methods are few of them very new and none of them original, but as they have largely proven their value it seems worth while collecting them for reference, as many of them are little used or their value generally appreciated.

Stomach.—It is not worth while going into the ordinary methods of examination for gastric chemical or functional integrity, as nowadays practically all internists are familiar with the routine examinations for hyper- or hypoacidity, with or without gastritis, achylia, hypermotility, retention, stagnation, dilatation, atony, etc., the use of inflation and *x*-ray examinations, and one is referred to any of the standard works for the detail of methods. There are, however, questions which arise in diagnosis of gastric conditions which are far from being capable of immediate and ready diagnosis; take for example, gastric ulcer, about which such an enormous amount has been written, and yet one constantly finds practitioners who are loath to make a posithe diagnosis without hemorrhage. The one primary symptom which must be kept in mind is pain, and it is a pretty safe rule, made the more emphatic by few exceptions, that according to Cohnheim[1], real pain referred to the stomach is practically always due to an organic lesion somewhere, and almost never to a neurosis. The most frequent causes, of course, of such pain are ulcer or erosions of the stomach or intestine, although one must exclude biliary disease, angina pectoris, intercostal neuralgia, epigastric hernia, or an organic lesion of the central nervous system with gastric crises.

Two methods are in vogue for deciding whether this pain is of gastric origin or not: First, by the giving of gastric sedatives during the pain, *e.g.* cocaine, orthoform, or chloroform water, any one of which, if given in sufficient amount, particularly on an empty stomach, will control the pain and so point to its true source; and second, the method which has for its object the calling forth of this pain by direct irritation, as in Bönninger's[2] test, by which, after washing out the empty stomach and examining the washings for blood, cells, etc., we introduce through the tube 200 c.c. of a

decinormal solution of hydrochloric acid (concentrated HCl 3.6 c.c. water 1,000 c.c.). If a gastric ulcer is present this acid solution will probably cause immediate pain; if the pain is due to other causes, the test will be negative. This method can also be used to show the progress and result of treatment. It is not so good, however, when there is a gastrosuccchorrhea, although in this condition, when there is pain, ulcer is usually the underlying cause of both conditions. Einhorn has recently proposed another method for diagnosing and locating ulcers of the stomach and duodenum (MEDICAL RECORD, April 3, '09). The duodenal bucket is swallowed in a gelatin capsule at 9 P. M., attached to a (English No. 5) silk thread and allowed to pass for 75 cm. from the lips. In the morning this is removed and the thread examined for a brownish stain caused by contact with the ulcerating surface. The distance of this spot from the lips points to the site of the ulcer. Ulcers of the fundus or greater curvature cannot be located by this test; but those of the esophagus cardia, lesser curvature, pylorus, and duodenum often can be.

One method of arriving at a diagnosis of either an achylia or a marked hypochlorhydria, without the aid of the stomach tube, is by the examination of the stool after a meat meal, for in this condition, as stated by Schmidt,[4] we find unchanged connective tissue present, the gastric secretion being the only one capable of digesting this substance. This method is particularly useful in old people, when we fear to pass the tube on account of brittle arteries and a possible cerebral hemorrhage from straining; again, in cases where we have reason to suspect an aneurysm of the aorta, under which conditions the tube should never be passed. The determination of the absence of acid is particularly important in those cases which are the subjects of a chronic diarrhea, so often found associated with achylia unaccompanied by any gastric symptoms. Sahli's so-called Desmoid test has the same object in view, and is made by giving the patient methelene blue in a small, thin, rubber bag, tied with catgut. If the gastric secretion is intact, the catcut is digested (being made of connective tissue) and the methylene blue excreted in the urine. This, however, has been found not to be absolutely reliable, and is more complicated than the method of Schmidt. The tests for occult blood in gastric contents and stool are too well known to need repetition here.

Gastric Cancer.—It is a lamentable fact, as stated by Kuttner,[5] that about 20 per cent. of all cases of carcinoma of the internal organs go unrecognized during life, despite the best means of diagnosis at our disposal, so when one suspects cancer of the stomach it is quite worth while trying to make a diagnosis, even though we may recommend an early exploratory laparotomy, as should always be done; since, too, we have come to know that the presence or absence of free hydrochloric acid throws little light on a possible diagnosis, it is necessary to turn in another direction for assistance. Salomon[6] has found that if the fasting stomach is washed out with 200 c.c. of water and the washing examined for albumin by the Esbach method, and if albumin in amounts of 1/3 to 1/2 per mille be found, this alone points strongly to cancer, also that if, by Esbach, we find from day to day that the albumin digestion of a test meal is growing progressively less, we have another valuable indication as to what the underlying condition may be. Of course, pyloric cancer invading the lumen of the outlet in common with similar effects from benign causes results in food retention, or when gastric motility is reduced from invasion of the musculature by the growth we have a consequent stagnation of food far beyond the period of normal digestion.

Intestine.—Although Hemmeter of Baltimore reports that in a number of instances he has been able to recover chyle by the passage of a long stomach tube through the pylorus, and Einhorn, by means of the duodenal bucket, it is doubtful if these will be of more than passing interest, as the digestion in the small intestine and the integrity of the pancreatic secretions are much better studied by other methods to be described later. Much, however, can be learned from the examination of the stool as to the intestinal functions, and for a detailed study of this one is referred to the translation of Schmidt's "Die Funktionsprüfung des Darmes mittelst der Probekost." The main points to be noted in the stool are, of course, the color, reaction, consistence, odor, the presence of starch and blood, pus and mucus, evidence of intestinal parasites, meat residue, besides a general microscopic examination for abnormal constituents. The two most important chemical tests are the test for fermentation of carbohydrates and for albumin in the form of mucus, not detectable by the microscope. The former test is carried out in an Einhorn saccharometer, or double fermentation tube, by mixing a small bit of feces with water, filling the tube and standing over night at body temperature, the presence of any gas, save a few small bubbles, denotes carbohydrate fermentation, which should be absent. (The details for the albumin test will be found in the footnote.*)

In this connection it must be remembered that the presence of an increased amount of indican in the urine, and other products of which it is an indicator, is due to albuminous putrefaction, not only of food protein, but probably also of intestinal mucus accompanying an enteritis or colitis, and from some investigations being carried on at present by the writer it seems likely that in some cases at least the excessive indican may be due to deficient tryptic digestion.

Pancreas.—The functions of the pancreas are of the utmost importance to normal digestion, and indeed, with proper food preparation, as is well known, complete digestion is possible in the intestine alone, in cases with entire loss of gastric secretion; so that in individuals with chronic diarrheas or with achylia we need to know the functional activity of this organ, for upon that will depend in large measure the accuracy of our prognosis and indeed treatment. The threefold functions of the pancreas of digesting carbohydrates by means of its amylopsin, protein by its trypsin, and fats by the ferment steapsin are all most important, and in attempting a diagnosis of suspected carcinoma of the pancreas, chronic pancreatitis, and to a lesser extent in acute pancreatitis, as well as in diabetes, it is quite imperative for us to know the working capacity of, at least,

*Test of Albumin in Feces (Schmidt). Twenty to thirty grams of feces are mixed with water in a mortar and after standing a few hours are filtered through a double filter paper. This cloudy filtrate can be cleared by filtering through infusorial earth. To this clear filtrate one adds carefully, drop by drop, 30 per cent. acetic acid, continuing it so long as any precipitate falls. (This precipitate is the normal nucleoprotein of the feces.) Filter this out through infusorial earth and to the new filtrate add a drop of potassium ferrocyanide; a fresh precipitate will prove the presence of albumin, which is pathological.

the carbohydrate and protein splitting enzymes. In addition to these functions we have to reckon with the internal pancreatic secretion in connection with the metabolism of sugars, especially in diabetes.

To accomplish this we have several forms of clinical tests. First, for the determination of the amyloptic integrity as well as that of the internal secretion. This depends on the power of the pancreas[7] to metabolize 100 gms. of dextrose properly, and is done as follows: On an empty stomach 100 gms. of dextrose are given in solution (best perhaps in weak coffee for a flavor) and the urine examined six hours later for sugar by Fehling's method. Normally the pancreas should be able to metabolize this amount completely, none appearing in the urine, which should be examined during the succeeding twelve hours.

Second, for tryptic digestion we have two reliable tests. In the first, bits of stool are planted on Loeffler serum in Petri dishes or on an ordinary throat culture tube, and placed in the incubator for twelve to twenty-four hours at 60° C. If tryptic digestion is normal, the surface of the serum will be pitted wherever the bits of stool rest, owing to the digestion of the surface of the serum at these points. If proper digestion has not taken place, the surface of the serum will be either smooth or show only slight depressions. This is an exceedingly simple and accurate test. This is also a measure of the other intestinal proteolytic ferments.

The second test, as described by Schmidt,[4] is the ability of the pancreatic secretion to digest the nuclei of meat cells, which is the only digestive secretion which can accomplish this, and is determined as follows: Small bits of meat are first partially hardened in alcohol stained with carmine; one such bit is enclosed in a very small gauze bag, securely tied. This is given to the patient to swallow and at the end of twenty-four hours, if the bag has not been passed in the stool, a cathartic should be given, as the meat must not remain in the intestine over one day. When removed, the meat is further hardened, embedded, and sections cut, or it may be examined fresh with acetic acid and methylene blue. If pancreatic, *i.e.* tryptic digestion is normal, the nuclei of the meat cells should have disappeared, but before diagnosing definitely a pancreatic lesion, all or nearly all the nuclei of the meat cells should have disappeared. An acute diarrhea interferes with this pancreatic test and the meat must not stay in the intestines over twenty-four hours, as simple putrefaction can cause an almost complete disappearance of the nuclei.

For the fat splitting ferment, steapsin, we have no simple chemical or clinical test, and the quantitative estimations are too complicated for the practitioner. The stools, when large, soft, foul, pale, and greasy, are, according to Robson and Cammidge, indicative of a failure in the action of the ferment in large part. If there is doubt as to whether a stool is fatty or not, it is simple enough to rub up a little of it with ether and pass it through a filter paper, which on subsequent drying of the water shows the paper to be greasy, if fat is present. The differential diagnosis between a fatty stool and a completely acholic stool will be referred to under the liver. Aside from the clinical picture, acute pancreatitis can often be diagnosed by a glycosuria or by Cammidge's [8] C. reaction, the latter depending on the presence in the urine of pentotozone. This, however, is too complicated for any but an expert chemist, so need not be further considered here.

The interpretation of all these results must be made with care, and it is always safer to do them in duplicate, thus following the chemist's rule to avoid mistakes. A positive dextrose reaction may indicate no gross lesion of the pancreas, but only a toxic affection. However, 65 per cent. of positive reactions are said to be due to disease, although the toxic influences must be ruled out. In pancreatic cancer we are more apt to have an azotorrhea[9] than in chronic pancreatitis, although if much meat is eaten and an enteritis is present, it may be hurried through the intestinal canal and appear in the stool in spite of a normal pancreas.

Liver.—It is unfortunate that in the consideration of the functional activities of this organ we have so few simple methods for testing them, particularly so, as the liver is the greatest biochemical laboratory of the entire system. On this account more diagnoses are hurled at the liver than at any other organ and results in placing at its door the larger portion of the ills, of a metabolic order, that the individual is heir to, and no doubt correctly so, but unfortunately not with intelligence. There are two methods in vogue for testing the liver. The first depends on the power of the normal liver of metabolizing 100 gms. of levulose, when given all at once, by the method already described in connection with the pancreas. Normally no trace of this levulose should appear in the urine by Fehling's method. With a pathological liver, in which the parenchyma is damaged, levulose will appear more or less promptly in the urine in greater or less amount, depending on the amount of functionating liver tissue remaining. This test is mainly valuable from a positive finding; a negative result is not conclusive, although Strauss[10] got 90 per cent. of positive reactions in patients with diseased livers; other investigators have not had such uniform results.

In the consideration of the excretion of bile in obstructive jaundice, with or without pancreatic disease, it is often a nice point to decide whether the acholic looking stools are really bile-free, and the occlusion, therefore, complete, or whether they are colorless from the large amount of fat, particularly as the pale stool may contain leucohydrobilirubin, a colorless bilirubin. Therefore, the test for bile pigment and this leucohydrobilirubin assumes more importance than might at first appear. To determine this a bit of feces is rubbed up with a concentrated solution of mercuric chloride. Normal feces are thereby colored red; leucohydrobilirubin also is stained similarly, feces containing unchanged bilirubin become green, therefore, an absence of the red or green reaction in fatty stools indicates a complete acholia.[11]

Still another method for testing the integrity of the parenchyma is more difficult and can only be carried out by a skilled chemist, as it depends upon the power of the liver to oxidize a certain amount of amino acid to uric acid, as recommended by Glessner.[12]

Suprarenal Organs.—As yet there is no established method for determining the functional activity of these glands, and the diagnosis must rest on clinical observation, although the presence of a lowered blood pressure, as determined by the sphygmomanometer is helpful in doubtful cases. The hypodermic tuberculin test may also be of assistance, unless there is evident tuberculosis in other organs, but should never be made if the patient is weak and evidently ill; one of the skin tests for tuberculosis can be used, of course, as well, and much safer.

although these latter are almost too delicate, even a healed tuberculous focus giving a positive reaction. A promising field for work may be developed in this by the determination in the lower animals of the effects of the injections of serum from these cases of suprarenal deficiency, as compared with the effects on blood pressure of normal serum injections.

Kidneys.—So much has been written about the disturbance of the functions of these organs, due to pathological lesions, including surgical conditions, or to purely functional derangement, that one is referred to almost any of the special books on renal conditions for further detailed information. The phloridizin and methylene blue tests for the functional activity of the kidneys may, however, be properly mentioned here. The former is a test for secretory ability rather than permeability,[13] and is based on the generally accepted view that phloridzin diabetes is due to the activity of the renal cells, and that a diminished or absent glycosuria means renal disease. These results are of more importance to the surgeon than to the physician. The results may be tabulated as follows:[14] "If after injecting 0.01 gm. of phloridzin, sugar appears in the urine in ten to fifteen minutes, it may be assumed that one kidney at least is functionating soundly. In continuing to examine the urine every fifteen minutes, a delay of thirty minutes in the appearing of sugar speaks for an essential functional disturbance in both kidneys. If no sugar appears in forty-five minutes, the functional disturbance is marked and would completely contraindicate any contemplated nephrectomy. Parenchymatous nephritis is an exception, for when albumin and casts are found the test is more prompt than normal and, therefore, is not synonymous with normal functioning."

The methylene blue test is advocated by many, and is supposed to test the renal permeability or the filtration power of the epithelium,[15] but in either of these tests it is necessary to keep in mind the clinical picture, as they have rather narrow limits of usefulness. This test is made as follows:[16] "If 0.05 gm. of methylene blue in a watery solution (1:20) be injected subcutaneously, it will be found, if the kidneys are healthy, that (1), the blue will appear in the urine within thirty minutes; (2), it will continue to be present for about forty to sixty hours; (3), about one-half the quantity injected will appear within twenty-four hours." This test is most useful in contracted kidney, while in the parenchymatous forms of nephritis, in amyloid and congested kidney results are too uncertain to be of much value. Its most ardent admirers now concede that really the most valuable part of the test is in determining the amount excreted in the twenty-four hours, as the time of its appearance after injection is too uncertain.

In conclusion I wish to call especial attention to one method of abdominal diagnosis, which, although purely clinical, is known and largely used abroad, but in spite of its great usefulness is seldom heard of here. This is the practice of making abdominal or bimanual vaginal examination of patients while in a hot bath. Unless one has tried this procedure it is difficult to conceive of its immense usefulness, for in many, if not most instances, the abdominal relaxation obtained is quite equal to that obtained under an anesthetic, with the added advantage that the patient can help the examiner by voluntary movements, such as deep inspiration, holding the breath, etc. This can be done in an ordinary bathtub, in water as hot as the patient can bear; or if it is desirable to have the patient higher in the tub, a long sheet may be let down over the tub into the water and fastened about the ends of the tub by knotting the corners under the rolling edge.

Most of the foregoing measures and tests in the diagnosis of abdominal conditions are simple, take little time, and with the exception of one or two of them can be done by the practitioner with very little apparatus, and certainly are of great assistance in the diagnosis of obscure intraabdominal lesions, although they must never be taken alone, separated from all clinical observation, for such implicit reliance on test tube and reagent will often lead one far afield.

STREPTOCOCCIC INFECTIONS OF THE THROAT—FURTHER OBSERVATIONS.

By RICHMOND McKINNEY, M.D.,

MEMPHIS.

PROFESSOR OF DISEASES OF THE NOSE, THROAT, AND EAR, COLLEGE OF PHYSICIANS AND SURGEONS OF THE UNIVERSITY OF MEMPHIS.

An article in which I reported a number of cases of streptococcic infection of the throat, which were observed by me during the winter then just past, was published in the *Journal of the American Medical Association* of May 29, 1909. Therein I commented upon the fact that I had also heard of a great many cases of streptococcic infection of the throat occurring in the surrounding country, and quoted to a considerable extent from the recent literature of this subject.

Since then I have had a number of other cases, and recently have seen three illustrative of the severity attained at times by this kind of infection. History of these cases is submitted herewith in full:

Case I.—Mrs. W. E. N., of Memphis, aged about thirty years, was seen by me June 14, 1909, in consultation with Dr. B. W. Fontaine. Two weeks previously while in Chicago, she paid a brief visit to a brother who was convalescent in a hospital from a condition that had been diagnosed as diphtheria. She was with him but a few minutes, and left shortly after for her home in Memphis. Three days ago she began to have sore throat, with fever off and on. The left tonsil was first affected, and then the right. Dr. Fontaine found a whitish exudate on the left tonsil, with considerable glandular

enlargement. A swab taken from this tonsil grew on blood serum what was shown on microscopical examination to be almost pure streptococci. The right tonsil also becoming painful, and the condition persisting, Dr. Fontaine asked me to see the case with him. Examination showed nothing on the left tonsil, this being true also of the right, but a small yellowish-white patch, apparently pseudomembrane, was seen on the right faucial pillar. There was marked glandular enlargement, especially on the right side, at this time. The patient had no fever. I removed a portion of the patch from the right faucial pillar, and inoculated a culture tube. The growth was found to be streptococci, as on the previous examination. The patient went on to uninterrupted convalescence with the simplest thereapeutic measures. Several young children of Mrs. N. were in the house with her and exposed to contagion without restraint, but enjoyed immunity.

Ordinarily this case would have been regarded as diphtheria, for the symptoms were such as would have been found in a mild case of this disease, and there was extratonsillar extension of the pseudomembrane, and furthermore, there was the history of exposure to diphtheria. Of course a question of diagnosis as regards the condition of Mrs. N.'s brother may be raised, and we were enabled to glean but very little of the clinical history in his case, but I believe that diphtheria was excluded in Mrs. N.'s case by the two negative bacteriological reports. The case impressed me at the time as being one of mild diphtheria, but Dr. Fontaine's very careful examination of the culture made from the exudate taken on the occasion of his first visit, and that grown from the pseudomembrane removed by me, had bacteriologically excluded this disease. Without the aid of the microscope, I believe the diagnosis would have been diphtheria. In this connection it may be argued that the streptococci had so overgrown the diphtheria bacilli that these occurred only occasionally, and were overlooked in the cultures, but this possibility was borne in mind and the cultures from the exudate and pseudomembrane were submitted to repeated microscopical examinations, the spreads being taken from different portions of the cultures. Furthermore, the growth on the media was not macroscopically characteristic of diphtheria cultures.

The next case that I shall describe perhaps gives an even more interesting clinical history:

Case II.—On September 16, 1909, I was asked by Dr. J. H. E. Rosamond of Memphis, to see with him Miss M, aged sixteen years, who began to suffer with sore throat two weeks prior to this visit. Five or six days after the beginning of this sore throat she developed a peritonsillar swelling on the right side, which was opened by Dr. Rosamond three days later, very little pus being found. The inflammation gradually subsided, but two days after the incision of the peritonsillar region the patient had a chill and rise of temperature and complained of headache. Examination of the throat by Dr. Rosamond revealed swelling of the peritonsillar tissues on both sides, with a whitish exudate over the tonsils. The pulse ranged from 112 to 136. The girl grew very weak and appeared to be in a grave condition. When seen by me with Dr. Rosamond about five o'clock in the afternoon, the temperature was 103°, pulse 130. There was a whitish exudate on both tonsils, which was easily wiped off, with no bleeding surface remaining. This exudate, I was informed by Dr. Rosamond, would recur in as short a space of time as thirty minutes. A swab had been taken from the throat the day before, showing streptococci in abundance, mixed with staphylococci. There was no albumin nor casts. There was considerable glandular enlargement on both sides of the neck. The patient's countenance was of that peculiar cast significant of grave infection. Dr. Rosamond had on the morning of this day given the patient 20 c.c. of antistreptococcic serum. I could see no indication for treatment other than supportive, with repetition of the serum every day until some effect was noticed. Dr. Rosamond reported to me that on September 17 the temperature was 100° in the morning, and the pulse 104, the appearance of the throat being about the same. That night he was called to see the girl hurriedly, and found that her temperature again was 104°. For several days the temperature continutd to fluctuate in about this proportion, and daily for four days an injection of 20 c.c. of antistreptococcic serum was given. The girl had fluctuating temperature, with septic chills and sweats for two weeks after I saw her, and it became a question of physical resistance in her fight against this severe infection. Even after her temperature curve became normal, and she apparently was beyond danger, the girl had these manifestations of sepsis. In this fight she finally won out, but there were many days when it seemed that she would succumb to the toxins which she had absorbed. The third case presents a more complicated picture.

Case III.—M. P., aged thirty, of London, England, an acrobatic performer in vaudeville, was seen by me December 20. Eight weeks ago he had a severe "head cold," which was complicated by what was pronounced by his attending physician to be frontal sinusitis, and for which his right frontal sinus was repeatedly irrigated, he also having been given two injections of mixed vaccines. Although not entirely well, he apparently was doing very satisfactorily until several days ago, when, while playing in Evansville, Indiana, he contracted a severe "sore throat," which was called tonsillitis. This condition began in the right side of the throat and then went to the left. Yesterday morning he was feeling very well, but early this morning he was awakened with a severe pain in the right side of the neck, which began to swell and grow stiff. Pain on moving the head was intense. He also suffered with dizziness when standing. Examination revealed some congestion of the fauces, but no indication of acute lacunar tonsillitis. The right sternocleidomastoid muscle was swollen from the mastoid tip to the clavicle, and brawny and painful to the touch. He had no fever at this time. It was very necessary for Mr. P. to give a performance that evening, since it was the opening of the week, and so nothing could be done for him at the time other than order an ice-pack to the neck. Under great physical strain and pain he went through his acrobatic turn, consisting of head balancing, etc., and the next day I was called to see him at his hotel, and found his condition much worse, in so far as the swelling and pain were concerned. There was still no fever. The uvula was edematous. The morning of December 22 there was still intense pain in the head and neck, the uvula was greatly swollen, and the temperature was 102° F. There was a free discharge of pus from the right side of the nose. The uvula was incised in several places, and

the patient was ordered to eat crushed ice. A capsule consisting of one-third grain codein and two and one-half grains each of phenacetin and quinine every three hours was to be taken, and a hot-water bag applied to the neck.

On December 23, at 9 A. M., the temperature was but 99.5° F., but the edema of the uvula, which had subsided after the previous incisions, again had returned. The uvula was incised repeatedly as before. Considerable albumin was found in the urine. The evening of this day I was called hurriedly, and found the patient with great swelling of the dermal covering of the nose and cheeks, with congested area looking quite erysipelatous. The nose was occluded by the swollen tissues about the orifices, and by the thick pus contained within. The temperature was 103.5° F., and the pulse 90. Ice was ordered for the face and head. Streptococci were abundantly found in the cultures from the nose and throat.

The next morning the swelling over the nose was greatly lessened, but had gone to the tissues below and above the eyes, almost closing these. The inflamed area was painted with phenol, neutralized with alcohol. Basham's mixture and calomel purging were ordered. The swelling of the uvula had entirely subsided, and the swelling and stiffness of the neck were almost entirely gone.

On December 26 the condition of the face was much improved, the temperature at 9 A. M. being 100.2° and the pulse 72. The following morning the temperature was normal, with a slight rise again in the afternoon. The third day after this the right side of the throat again became inflamed, with peritonsillar swelling and edema of the uvula. Incisions of the uvula, and into the fossa supratonsillaris, were made, but no pus was found. The temperature rose in the afternoon, and continued for several days. A third effort to find pus in the supratonsillar region was successful, a pocket being emptied. Convalescence then was uninterrupted.

This unquestionably was a case of streptococcic infection of the right frontal sinus, with secondary involvement of the cellular tissues of the throat and face.

In these latter cases we have examples of typical streptococcic infection, with which the entrance of no other factor could complicate the diagnosis, and the clinical history is similar to others that I have seen, and of cases which I have seen reported. One rapidly fatal case reported by Marschik, quoted by me in my previous article already referred to, showed nothing but the streptococcus as the etiological factor. We have in most of these cases, as is true of practically every bacteriological condition, a mixed infection, and these streptococcic infections as a rule have the staphylococcus associated with them, but we can regard the latter microorganism as merely incidental, and as having very little if anything to do in causing the serious symptoms found in these cases.

The streptococcus is found in normal throats, apparently inert, but it seems speedily to be whipped into activity by inflammatory alterations of the mucous membrane. There seems, however, to be some lessened resistance which admits of this, for every inflammation of the throat where streptococci are found does not assume this virulent type, any more than do all cases where people carry the diphtheria bacillus in their throats develop diphtheria. What this peculiar condition is we are yet at a loss to explain, but there remains the fact that we must recognize a character of inflammation of the throat associated with the streptococcus as the causative factor which may assume a very malignant type. In the second case just reported the resistance had been lessened by a condition of hyperthyroidism, which had materially improved under treatment.

The question may very well be raised as to the influence of antistreptococcic serum in this condition. With reference to the value of serotherapy in streptococcic infections, Dewatripont,* in reporting some cases of streptococcic infection of the lacrymal canal of nasal origin, says that *in vitro*, the serum of Marmorek is antitoxic; that one c.c. of streptococcus toxin, killing a rabbit in three or four days, becomes inactive in the presence of three to five c.c. of serum. *In vitro* Marmorek's serum has no bactericidal property when brought in contact with the streptococcus, but does not exhibit, according to Bardet, in a feeble degree agglutinative property, it being necessary to bring in contact with the culture at least one-third of its volume of serum. If two c.c. of Marmorek's serum be injected under the skin of a rabbit twenty-four hours after inoculation of the latter with a millionth of a c.c. of a streptococcus culture of which one ten-millionth c.c. is surely fatal, the animal is preserved. Furthermore, if two c.c. of the serum be similarly injected in an animal inoculated three hours before with a dose ten times fatal, or if five c.c. of the serum be injected in a rabbit five hours after injection of the same dose of virus, the rabbit is preserved. But these results obtained in animals do not necessarily follow with human beings. I have used the serum in a number of cases, and yet the question of its value still remains open to me, for I have never seen it exercise any immediate beneficial influence in any of these cases, but yet I could not say that without its use there would not have been a fatal termination in the cases where it was used. In the fulminating or rapid type of such infections, I believe the serum would have practically no effect, for the toxemia is general and too pronounced for the serum to produce decided results. Where we have a lingering type of infection, such as that in the second case reported by me, we have a better opportunity to use the serum, and to get its beneficial effects, if it has any.

Streptococcic infections assume a different type in different individuals, and for this reason a perfect stock serum has not yet developed. For instance, we have erysipelas and scarlet fever, supposed to be caused by the same organism, yet the great difference in these diseases precludes the use of a universal serum. Perhaps autogenous sera, could they be prepared, would act well in streptococcic infections, as also might one of sufficient polyvalence. These infections and the angina of scarlet fever look like one and the same thing, clinically and bacteriologically, yet it cannot positively be said that they are identical, even though the etiological factor be the same.

In the light of our present therapeutic knowledge, the treatment of these cases after all resolves itself into supportive measures, bracing the patient's vitality in the effort to resist the severe general infection which results from asorption of the toxins from the point of entrance.

THE ABSTRACTION OF THE CALCIUM SALTS OF THE LIPOIDS CIRCULATING IN THE BLOOD FOR THE PURPOSE OF THE NEUTRALIZATION OF THE ORGANIC ACIDS, THE CAUSE OF LIPEMIA IN DIABETES MELLITUS.

By JENNIE G. DRENNAN, M.D., C.M.,
CHICAGO.

Diabetes mellitus is supposed to be a disease in which, owing to a diminution or suppression of the secretion of Langhans cells in the pancreas—an internal secretion—the oxidation of the sugar in the muscles is interfered with and consequently there is an increased amount of sugar in the blood, which is prone to undergo decomposition into organic acids, causing an acidosis. Nature makes an attempt to neutralize these acids and to a marked degree at first is successful; but it is a case of robbing Peter to pay Paul, and in the place of acids in the blood there is fat. I do not think that it is too great a stretch of the imagination to think that at least one source of the neutralizing substance shall be the lipoids circulating in the blood, that from these the calcium is abstracted and combined with the organic acids. If this is the case, then neutral fat will appear in the blood. The theory, that this fat in the blood is due to fatty degeneration of the blood corpuscles, has been advanced and while I see no reason why these cells should not undergo a certain amount of fatty degeneration in common with all other cells, still I am not inclined to think that this is the cause of lipemia, though in this condition in which I think the calcium is used up in neutralizing the organic acids, no doubt this fat formed in these corpuscles remains uncalcified if I may use such a term in connection with the formation of lipoids; but instead of existing in a free state as an emulsion of fat in the blood it would exist as an infiltration of the blood cells just as it does in other tissue cells, when it is not combined with calcium salts to form lipoids—fatty infiltration of liver and kidney cells. According to my theory, this fat in the blood must have once been combined fat—lipoids—in order to have been conveyed to the blood; but I am inclined to thing that the amount of lipoids circulating in the blood is not so great in this disease as is normally the case, for the increased fatty infiltration of such organs as the kidneys and the liver would indicate that the fat found there is not as normally combined with calcium and either stored as lipoids in these organs or carried by the circulation to other regions of the body such as the subcutaneous tissues, which in this disease are poorly supplied with fat, which fact cannot wholly be explained by other theories. In all probability a considerable proportion of the calcium salts is combined with these acids before they have had time to reach such tissues as have undergone a fatty degeneration; then moreover, no doubt a considerable amount of the calcium, which has combined with the fat of the food during the process of digestion, when these lipoids are being carried by the blood stream to the various organs as nutriment, will be abstracted from the lipoids and neutral fat will be present in the blood.

Summary:

1. The lipemia of diabetis mellitus is due to the abstraction of calcium salts from the lipoids circulating in the blood.

2. This abstraction is an attempt on the part of nature to neutralize the organic acid, which result from the imperfect oxidation of the sugar in the body, fat in the blood being the lesser of two evils. Fat embolism may result in the lungs, but may exist quite extensively without causing serious symptoms.

3. The indications in diabetes would be an increased administration of calcium salts, in the one case sufficient to neutralize the acids and to unite with the neutral fat and in the other case sufficient to unite with the neutral fat.

A PRACTICAL METHOD OF ANESTHESIA FOR THE REMOVAL OF ENLARGED TONSILS AND ADENOIDS, AND FOR OTHER OPERATIONS ON THE HEAD.

By M. ERNEST JUTTE, M.D.,
NEW YORK.

Many surgeons have felt the want of a satisfactory method of anesthesia in operations on the head, particularly for those cases where an interrupted narcosis is undesirable or even objectionable. With the ordinary methods of narcosis in operations in the mouth, the mask has to be removed to make room for the surgeon who often finds himself hampered by the untimely awakening of his patient. I should like to call attention to the following simple method of obtaining a continuous anesthesia without interfering materially with the surgeon's manipulations. The apparatus used consists of a wide-mouthed four- or six-ounce bottle with a doubly perforated rubber stopper, which transmits two glass tubes, a long afferent one, reaching close to the bottom of the bottle, and a short efferent one, which just passes through the rubber stopper. The long tube is connected with a double bulb while the short tube is joined by means of rubber connection to a hook-like metal mouthpiece such as is used by dentists, under the name of "Rose's saliva ejector." It is best to initiate narcosis by the drop method with ether or anesthol and to put the patient well under. The metal piece is then hooked around the mouth gag and the vapor, which is generated by forcing air through the anesthetic, is projected into the mouth of the patient. In this manner narcosis can be kept up for a long time and thorough work can be done with the least possible interference with the operator. Instead of the mouthpiece one may use two thin rubber tubes joined by a Y-shaped tube; these are inserted through the nostrils as in Crile's method.

Studies of Diarrhea in Infants.—Elie Metchnikoff has made a study of the causation of diarrheas in infants, by inoculation of rabbits and chimpanzees with the fecal material of an infant sick with cholera infantum. These animals contracted a diarrhea similar to that of the child. In the feces he found that the germ most frequently present was the proteus, which is well tolerated by adults, but causes diarrhea in infants. He believes that it is this organism that causes summer diarrheas. As to how the child becomes infected he shows that the organism is seldom found in milk, and hence sterilization is not of great importance. But it is found on all fruits and vegetables that are exposed to the open air, on cheese, and the upper layer of meats. Flies take a great part in conveying the germs to food. The preventive measures are the washing with boiling water of all fruits and vegetables, and the careful cleansing of the hands before handling food. The destruction of flies and municipal sanitation are important.—*Gazette Médicale de Paris.*

THE NEXT PHARMACOPEIA.

THE pharmacopeial convention which meets in Washington on next Tuesday will be far more important than any of its predecessors, since its deliberations have now to do with the making of an official standard, and not merely with an advisory work, the prescriptions of which one could regard or not as he pleased. Hitherto the book has been one that had little interest for physicians, many of whom doubtless have never seen a copy of it, and outside of perhaps a dozen or twenty of the most commonly used drugs could not tell what drugs are official and what are not. Now it is different. The passage of the pure food and drug law and the discoveries which preceded and followed the passage of this law have opened the eyes of physicians to the fact that many of the drugs they had prescribed were never taken by their patients or were not taken in the desired dose. They have consequently begun to look up to the hitherto despised or neglected Pharmacopeia as their protector and the protector of their patients, and they are interested in the proceedings of the convention which is to determine upon the changes necessary to make the book worthy of the dignity it has now acquired.

The most important matter to be decided is that of the drugs to be included in the new edition. This matter is one in which the medical members of the revision committee will naturally have the strongest voice, yet there may be danger in yielding to their wishes entirely. It is well known that certain members of the profession are anxious to exclude from the Pharmacopeia some drugs which they regard as useless or superfluous and which are lagely used by the laity without the physicians' prescription. They seem to think that if these drugs are excluded they will no longer be prescribed. They forget apparently that scores of non-official drugs are in constant use and that a physician who thinks acetanilid, for example, is a useful drug will prescribe it after it is excluded from the Pharmacopeia just as he did before it was admitted. The only effect of excluding it will be to remove the safeguard of a standard of purity; then, no longer trusting the average retail pharmacist, or rather doubting his ability to procure a pure drug, the user of acetanilid will be led to prescribe some proprietary form of it made by a trustworthy manufacturer, and the patient will get hold of the proprietary name and prescribe for himself in the future. Thus will the would-be purifiers of the Pharmacopeia and regulators of therapeutics defeat their own object. If the Coudray Bill, now we believe in the House Committee on Inter-State and Foreign Commerce, passes the committee and the Congress, it will matter less what the committee on revision of the Pharmacopeia decides to do, but if the Pharmacopeia is to remain the only standard, the aim of the revision committee should be, not to reduce the number of official drugs, but to include all that are in common or more than semi-occasional use. There cannot be too many drugs in the Pharmacopeia if this is to be the only standard for the crude drugs and their alkaloids. Nor can the revisers of the Pharmacopeia hope that physicians will consult it or respect its authority if it deliberately excludes a large number of the drugs which they use. It has been foolishly put forth that the Pharmacopeia is a privately owned work and is under no obligation to provide standards of purity for the U. S. Government. If that is the stand which the owners of the Pharmacopeia are going to take, then the framers of the Pure Food Law will have made a great mistake, and the sooner the Coudray Bill, providing that the Department of Agriculture shall fix a standard for all drugs not contained in the Pharmacopeia, is passed, the better for the science of therapeutics and for the health and safety of the community.

ORAL HYGIENE.

IN every civilized country of the world, it is now recognized that the care of the mouth and teeth is a very important factor of public health. In uncivilized countries teeth are good and to pay attention to oral hygiene would be a superfluous act, for sad to relate it is only in civilized lands that the reverse is the case, and the more highly civilized a country is the more frequently will the need of prophylaxis of the mouth be emphasized. All the leading nations of Europe have instituted measures for the care of the mouth and teeth, and the subject of oral hygiene is receiving attention in the elementary schools of European countries.

According to Public Health Reports, April 8, a national campaign on oral hygiene is to be undertaken in this country. In fact, such a campaign was opened in Cleveland, Ohio, on March 10, at which meeting, at the instance of President Taft, Passed Assistant Surgeon C. W. Wille of the Public Health and Marine Hospital Service was present in a representative capacity. Dr. Wille explained what the objects and methods of the campaign were and pointed out that the State of Massachusetts was causing to be delivered popular lectures on dental hygiene and prophylaxis in some of the public schools. The City of New York maintains clinics for the care of the teeth of the children of the indigent poor, and the city of Rochester maintains one clinic, while some of the cities of New

Jersey, Indiana, Illinois, Mississippi, Iowa, Minnesota, Georgia, and Washington have instituted dental examinations. Cleveland has shown herself particularly enthusiastic in the subject of oral hygiene and has instituted a system of school inspection, methods for treating teeth of poor children, and of instructing parents, teachers, and scholars by means of practical and illustrated talks in matters pertaining to dental hygiene. The plans pursued in Cleveland have been attended with a considerable amount of success, and under the auspices of the national association it is intended to follow a similar course in carrying this campaign into the various cities and States of the Union. The purpose of the campaign is to bring the importance of this subject fully and frankly before parents, educators, social workers, and philanthropists to invite the public to an open discussion on oral hygiene and to determine how best to further the popular movement for the better care of the mouth and teeth. New York City is not behind in this good work, and much is to be hoped for in the way of popular education from the Dental Hygiene Conference and Exhibit which will begin on Thursday of next week. The exhibit will bring home to all who see it the necessity and advantage of caring for the mouth, and this will be emphasized in the evening conferences.

There is little doubt that good health is largely dependent upon the state of the mouth. In cases in which the mouth is in a foul condition, intestinal disturbance is sure to exist. The stomach acts on the mouth and the mouth reacts on the stomach, and it may be definitely stated that a person whose mouth and teeth are in a bad condition will suffer from disorders of the digestion. Therefore, it is a question of public concern of much moment that the teeth of the rising generation should be in good order, and for this reason among others the national campaign on oral hygiene is to be highly commended.

The Dangers of Paper Currency.

Paper money, as an avenue by which disease can be transmitted, has been an object of suspicion for some time. Indeed, this particular form of exchange has been shown, more or less conclusively, to be under favoring conditions an actual menace to the health of the community. Hilditch of the Sheffield Laboratory of Bacteriology and Hygiene, Yale University, and Park of the Research Laboratory of the Board of Health of New York have demonstrated that dirty paper money is "similar to other paper and rags and capable of carrying living tubercle and diphtheria bacilli for some days or longer." Hilditch, however, does not regard the danger as very great. He obtained twenty-four bills, the very dirtiest he was able to procure, and subjected them to a minute examination, the outcome being that he found the average number of bacteria in each of twenty-one bills to be 142,000, while by far the most common forms were the varieties of the pyogenic staphylococci. Further, it was established by subsequent experiments that these organisms were not in possession of their full virulences. The publication of these results was apt to create a feeling of confidence in the comparative harmlessness of the dirtiest paper money, or, at least, to seem to demonstrate that as sources for spreading infection such was not greatly to be feared. In a recent issue of the *Popular Science Monthly*, A. Cressy Morrison writes to point out that the menace of paper money must not be wholly judged from the virulence or the nature of the germs discovered. He pertinently draws attention to the fact that the infection of drinking water with the germs of typhoid fever should not be estimated from the number of the *Bacilli typhosi* found, for if that were the case water would be seldom condemned, and those bacilli are seldom discovered. In brief, Morrison contends, and it appears contends with justice, that it is not so much the question of the virulence or even of the nature of the organisms found on paper money, but that experiments have established that money is a medium of bacterial communication from one individual to another. In order, therefore, to elucidate the matter, paper money known to have been exposed to contamination by highly infectious organisms should be examined by scientific experts. It has been ascertained that money can be infected by handling, it has also been shown that the germs of diphtheria and tuberculosis may live on infected bills for several days. Morrison says: "It seems but a step, then, to the final demonstration of the actual transmission of these and similar diseases by money in circulation and to the prevention of such spread of disease by the proper measures to eradicate such possibilities." There is little doubt that disease is spread in ways that we know not, even in these times of advanced research. If paper money does spread disease, though but to an extremely small extent, this is reason sufficient to insist upon the more rapid withdrawal from circulation of soiled bills and the issuing of new and clean notes. The results of more minute and exhaustive investigations into the question of infected paper money as a means of spreading disease should be interesting and valuable.

New York State Department of Health.

The annual report of the New York State Department of Health naturally contains matter of much interest to medical men. The pollution of streams, rivers, and lakes in the State is, of course, pointedly referred to, and the need for the adequate protection of our public water supplies is dwelt upon earnestly. Progress is to be noted in sanitary education, both in the public schools and in the colleges and universities of New York State. The department has interested itself greatly in popular educational work for the prevention of tuberculosis and with success. After alluding to the fact that rabies in man is increasing in this country, the report goes on to state that "investigations and developments in the therapy of rabies have progressed so far in recent years that the department is now in a position to provide a suitable therapeutic substance for treatment of all cases occurring within the State that may require the department's aid." In New York City diphtheria has been somewhat prevalent. During the past year more than sixteen thousand cases of the disease were reported with a death rate of thirty-eight per 100,000 population. In the rural districts the cases were much fewer, and the death rate was less than ten per 100,000 population, all of which goes to show that

diphtheria is a disease of large cities. Reference is made in the report to the menace of diphtheria carriers. There have been in recent years several extensive outbreaks of acute anterior poliomyelitis in the State, in the autumn of last year a rather alarming outbreak of the disease occurred in the vicinity of Gouverneur. It is pointed out in the report that there is reason to place acute anterior poliomyelitis among communicable diseases, since there is certain evidence that it may be transmitted from one person to another, and that it prevails in the form of local epidemics. The division of publicity and education of the department has done very useful work. The Monthly Bulletin has had a large circulation and has undoubtedly exercised a favorable educational influence. Numerous circulars have also been issued and have been in constant demand. These are a very valuable means for disseminating throughout the community information concerning the more common of the communicable diseases.

Tuberculous Articular Rheumatism.

During the present generation the understanding of the word rheumatism has undergone a great change. From a general class comprising practically all painful conditions in muscles and joints, the various forms of arthritis have gradually been split off until we now recognize under the term rheumatism an acute infectious disease, possibly of bacterial origin, one symptom of which is an arthritis amenable with a definite specificity to sufficiently large doses of salicylic acid or its salts. Among those forms of acute arthritis which have been separated from rheumatism there is still considerable confusion. Gonorrheal arthritis has become well established, and the infectious arthritides, meningococcus arthritis, septic and toxic arthrides, and many others are constantly coming in for more and more attention. In the *Berliner klinische Wochenschrift for* March 14, 1910, E. Melchior calls attention to the rôle which he believes may be played by the tubercle bacillus in the production of an acute serous polyarthritis. His paper is of value especially from an historical standpoint, as he cites cases reported by various writers of instances in which joints have become acutely inflamed in association with either general miliary tuberculosis or a local tuberculous lesion in other parts of the body, these sometimes clearing up entirely and in other instances one joint remaining infected, suppurating, and showing the typical picture of a tuberculous joint. The case which the author reports is that of a young woman who, following an extensive tuberculous disease of the jaw bone, developed a polyarthritis. The final diagnosis of the nature of the disease was made by the finding in the patient's blood of the tubercle bacilli. Such a means of diagnosing the condition as a tuberculous articular rheumatism, in the light of the skepticism at present prevalent upon the question of tuberculous bacteremia and especially in the presence of other foci of tuberculosis, greatly vitiates the value of the author's paper, and especially the authenticity of his particular case. In his historical review, however, he has referred to a sufficient number of more scientifically proven cases, at least very strongly to suggest that the tubercle bacillus may cause an acute transient serous polyarthritis, just as it is well known it may produce serous pleuritis or peritonitis.

News of the Week.

Physicians in Command of the Army.—With the assumption by General Leonard Wood of the office of Chief of Staff of the U. S. Army and the advancement of Major-General F. C. Ainsworth to become ranking Major-General, the two highest positions in the army are held by physicians who entered the line from the medical service. General Wood was graduated from the Harvard Medical School in 1884 and immediately entered the medical corps of the army. At the outbreak of the Spanish-American War he became colonel of the Rough Riders, and in 1908 was promoted by Mr. Roosevelt to be Major-General. General Ainsworth was graduated from the medical department of the New York University in 1874, and also immediately entered the medical corps of the army as assistant surgeon. In 1892 he was made Colonel and Chief of the Record and Pension Office of the War Department. From that time on his advance has been rapid. He was made a Brigadier-General in 1899, and in 1904 was made a Major-General and Military Secretary of the Army.

The New York State Department of Health announces a public health laboratory course to be given at the State Hygienic Laboratory in Albany May 9-14, open to the Health Officers of the State, free of cost. The course will include lectures and practical laboratory work upon various subjects connected with public hygiene, including bacteriology and chemistry of water analysis. The department also announces that the quarantine station in New York Harbor will be open to any health officer of the State during the coming summer. The visiting health officers, who will be supplied with quarters and sustenance, will be allowed to take an active part in all of the work of the station.

Deaths from Street Accidents.—According to the report of the National Highways Protective Society, the mortality from street accidents to children in New York for April was the highest on record. During the month 5 persons were killed by electric cars, 9 by automobiles, 3 by wagons, and 1 by a runaway horse. Thirteen of these 18 persons killed were children under 16 years of age. Nine were killed in Manhattan, 5 in Brooklyn, 2 on Staten Island, and 2 in the Bronx. None was killed in Queens.

Examination for the Indian Service.—The United States Civil Service Commission announces an examination on June 1, 1910, to secure eligibles from which to make certification to fill a vacancy in the position of physician, $1,000 per annum and quarters, in the Indian Service, Pine Ridge Agency, South Dakota, and other vacancies requiring similar qualifications as they may occur in any branch of the service. The age limit is 20 to 40 years, on the date of the examination. Applicants should apply for a copy of the Manual of Examinations and the proper application forms to the United States Civil Service Commission, Washington, D. C.

Examination for Medical Internes in the Government Hospital for the Insane.—The United States Civil Service Commission announces an examination on June 15, 1910, to secure eligibles to fill at least two vacancies in the position of medical interne (male), Government Hospital for the Insane, Washington, D. C., at $600 per annum each, with maintenance. Applicants must not have been graduated more than two years prior to the date

of the examination unless they have been continuously engaged in hospital, laboratory, or research work along the lines of neurology or psychiatry since graduation, which fact must be specifically shown in the application. Both men and women will be admitted to this examination. The age limit is 20 years or over on the date of the examination. Applicants should at once apply to the United States Civil Service Commission, Washington, D. C., for application Form 1312.

A Hearing on the Department of Public Health.—Nearly one hundred representatives of insurance, public health, educational, and medical societies appeared before the Senate Committee on Public Health and National Quarantine April 29 in support of the bill by Senator Owen of Oklahoma creating a Federal health department. Among the speakers were Drs. William H. Welch of Baltimore and Dr. George Y. Porter, Health Officer of the State of Florida.

The Educational Alliance in East Broadway in New York had a mass meeting recently at which the inhabitants of the East Side were urged to leave that overcrowded district and move to the open boroughs. Especial attention was called to the prevalence of tuberculosis in this district and the difficulty of cure and liability to relapse of those living under such conditions.

Auscultation by Telephone.—A dispatch from London describes an experiment with an apparatus which when attached to a telephone enabled physicians in the Isle of Wight to hear the heart sounds of a woman in London one hundred miles away.

Bulletin on Drug Habits.—Farmers' Bulletin No. 393, which has recently been issued by the U. S. Department of Agriculture, deals with the dispensation of the habit-forming drugs, especially as sold in soothing syrups, asthma cures, and other proprietary medicines advertised as harmless. Photographs of the original packages of some of the more dangerous of these drugs are included in the report, which is said to be the first of a series to be published on this subject by the Department of Agriculture.

The Saturday and Sunday Fund for the year 1909 was apportioned among the various charity hospitals of New York City at a meeting held in Mayor Gaynor's office recently. The total amount of the fund for the year is $76,000. The largest sums, which are apportioned according to the amount of free work done at each hospital, were given to the Montefiore Home, and Mount Sinai Hospital, which received $7,600 and $7,551, respectively.

The Dental Hygiene Council of New York, with the cooperation of the Children's Aid Society, the Association for Improving the Condition of the Poor, and the Charity Organization Society, will hold a Dental Hygiene Conference and Exhibit in the Metropolitan Life Building, May 12 to 18, for the purpose of emphasizing the importance of better care of the mouth and teeth. The exhibit will be open day and evening, including Sunday, May 15. Conferences will be held each evening of the week except Sunday.

The Johns Hopkins Medical School Alumni held their first reunion during the two days commencing May 6, at Baltimore, Md. The reunion included clinics and demonstrations, an alumni banquet, and class meetings, at which permanent organizations were formed.

The Samuel D. Gross Prize of the Philadelphia Academy of Surgery for 1910, amounting to $1,500, has been awarded to Astley Paston Cooper Ashhurst, M.D., of Philadelphia, for an essay entitled, "An Anatomical and Surgical Study of Fractures of the Lower End of the Humerus."

The Mount Sinai Hospital.—The following changes and new appointments have been made in the staff of Mount Sinai Hospital: Dr. Herbert L. Celler, Assistant Adjunct Visiting Physician; Dr. Reuben Ottenberg, Assistant in Clinical Microscopy; Dr. Israel Strauss, Assistant Adjunct Visiting Neurologist; Dr. Harold Neuhof, Adjunct Admitting Physician; Dr. Julian J. Meyer, Assistant Adjunct Admitting Physician. The George Blumenthal, Jr., Fellowship for 1910 has been awarded to Dr. A. A. Epstein, Assistant in the Department of Physiological Chemistry.

The Boston University School of Medicine.—The annual "Clinical Week" exercises of the Boston University School of Medicine will be held at the school buildings during the week of May 30 to June 4. These consist of thirty-six clinics, clinical lectures, demonstrations, and lectures covering in a brief form the various departments of the medical sciences. The school has also established a formal series of post-graduate courses to extend throughout a part of the summer.

The Wayne County Medical Society is at present negotiating for the purchase of a house in Detroit, which may become the permanent home of the society.

Washington University, according to a dispatch from St. Louis, has recently received an endowment fund of $6,000,000.

The University of Oklahoma has completed its consolidation with the Epworth College of Medicine. Hereafter the first two years of the course will be held at Norman and the last two years in Oklahoma City. Dr. Charles Sharp Bobo of Norman, the professor of forensic medicine, will be the dean of the medical faculty, and Board of Control of the Oklahoma City branch will consist of Dr. Archa Kelly West, formerly dean of the Epworth College of Medicine; Dr. A. L. Blesh, and Dr. R. M. Howard.

Bill for Letchworth Village Signed.—Governer Hughes has signed the bill of Assemblyman Merritt appropriating $179,000 for the beginning of construction of Letchworth Village, the new State institution at Thiells for the care of epileptics and idiots. $65,000 of the appropriation to be available immediately and the remainder on October 1 next.

The Central Maine Association for the Relief and Control of Tuberculosis was organized at a meeting held at Waterville, Maine, April 21, 1910.

Monument to Dr. Long.—The monument erected by the Georgia Medical Society at Jefferson, Ga., in honor of Dr. Crawford W. Long and his pioneer work with ether anesthesia, was unveiled on April 21, 1910.

A Dinner to Dr. Marx.—A testimonial dinner was tendered to Dr. Simon Marx at the Hotel Savoy, in New York, on April 29, by professional friends. A gold plaque was presented to Dr. Marx in honor of the occasion.

General Nelson H. Henry, who has recently been appointed Surveyor of the Port of New York by President Taft, is a graduate of the College of Physicians and Surgeons of Columbia University

in 1879, and for many years practised medicine in New York City. General Henry has been a member of the National Guard since 1883, served as a member of the medical corps at Camp Black and Tampa during the Spanish War, and at present is Adjutant-General of the National Guard of New York.

Dr. Thomas E. Satterthwaite of New York was the guest of honor of the Washington Medical and Surgical Society at their annual dinner on May 4. The subject of his address was "Some Newer Conceptions of Myocardial Disease."

Dr. W. J. Brown of Boston has resigned his position in charge of the south department of the Boston City Hospital.

American Dermatological Association.—At the meeting of this Association, held at the Arlington Hotel, Washington, D. C., May 3, 4, and 5, 1910, the following officers were elected for the ensuing year: *President,* Dr. Douglass W. Montgomery of San Francisco; *Vice-President,* Dr. Martin F. Engman of St. Louis; *Secretary and Treasurer,* Dr. James M. Winfield of Brooklyn; *Councillor-at-Large,* Dr. Charles J. White of Boston. Boston, Mass., was decided on as the next place of meeting.

The New Hampshire Medical Society will hold its 119th annual meeting at Memorial Hall, 21 Center street, Concord, May 12 and 13, 1910. The president of the society is Dr. Frank Blaisdell, and the secretary is Dr. D. E. Sullivan of Concord.

The Hampden District (Mass.) Medical Society held its annual meeting at Springfield April 19, 1910. Officers were elected as follows: *President,* Dr. H. W. Van Allen; *Vice-President,* Dr. R. H. Seelye; *Secretary and Treasurer,* Dr. P. M. Cort.

The Hempstead County (Ark.) Medical Society met at Hope, April 13, 1910, and elected the following officers: *President,* Dr. T. J. Garner; *Vice-President,* Dr. J. L. Kelly.

The Rock Island County (Ia.) Medical Society, at its annual meeting held at Davenport April 12, elected the following officers: *President,* Dr. H. S. Bennett of Moline; *Vice-Presidents,* Dr. W. L. Eddy of Milan, and Dr. J. E. Asay of Rock Island; *Secretary,* Dr. Albert N. Mueller of Rock Island; *Treasurer,* Dr. A. T. Leipold of Moline.

The Tolland County (Mass.) Medical Society, at a meeting held at Rockville April 19, elected the following officers: *President,* Dr. Cyrus E. Pendleton of Hebron; *Vice-President,* Dr. Francis M. Dickinson of Rockville; *Secretary and Treasurer,* Dr. E. P. Flint of Rockville; *Councilor,* Dr. T. F. Rockwell of Rockville.

The Washington County (Ia.) Medical Society held its thirty-seventh semi-annual meeting at Washington, Ia., April 12, and elected the following officers: *President,* Dr. J. H. Hull; *Secretary and Treasurer,* Dr. W. H. McLaughlin; *Censors,* Drs. George W. Hay and George W. Dash.

The Brockton (Mass.) Medical Society held its annual meeting April 14 and elected the following officers: *President,* Dr. E. C. Frost; *Vice-President,* Dr. Harry A. Chase; *Secretary,* Dr. R. A. Elliot; *Treasurer,* Dr. E. E. Goodwin.

The Davidson County (Tenn.) Medical Society held its annual meeting at Nashville, April 5. The following officers were elected: *President,* Dr. J. M. King; *Vice-President,* Dr. Robert Caldwell; *Secretary and Treasurer,* Dr. W. C. Dickson.

The Rock Springs (Wyo.) Medical Association was organized recently with the following officers: *President,* Dr. E. S. Murray; *Secretary,* Dr. J. A. Edwards; *Treasurer,* Dr. E. S. Lauzer.

The Tennessee State Medical Association held its annual meeting in Memphis and elected the following officers: *President,* Dr. John A. Witherspoon of Nashville; *Vice-Presidents,* Dr. J. J. Faller of Olive Springs, Dr. Richard A. Barr of Nashville, and Dr. J. H. E. Rosamond of Memphis; *Secretary,* Dr. George W. Price of Nashville; *Treasurer,* Dr. W. C. Bilbro of Murfreesboro; *Board of Trustees,* Dr. W. C. Bilbro of Murfreesboro, Dr. B. D. Bosworth of Knoxville, and Dr. E. C. Ellett of Memphis.

The Springfield (Mass.) Academy of Medicine held its annual meeting on April 12 and elected the following officers: *President,* Dr. O. W. Roberts; *Vice-Presidents,* Dr. F. W. Chapin and Dr. Philip Kilroy; *Treasurer,* Dr. H. C. Martin; *Director,* Dr. Flood of Monson; *Censor,* Dr. Lawton Brooks.

The Brazoria County (Texas) Medical Society was organized in Angleton, April 15. Dr. S. B. Maxey was elected president.

The Belknap County (N. H.) Medical Society held its annual meeting at Laconia, April 11, 1910. The officers chosen for the ensuing year were as follows: *President,* Dr. Frank A. Easton; *Vice-President,* Dr. W. H. True; *Secretary and Treasurer,* Dr. A. H. Harriman; *Censors,* Dr. G. H. Saltmarsh, Dr. J. G. Quimby, and Dr. J. C. Huckins.

The Craighead County (Ark.) Medical Society was reorganized at a meeting held at Jonesboro, April 20. The following officers were elected: *President,* Dr. W. W. Jackson; *Vice-President,* Dr. D. A. Pelton; *Secretary,* Dr. C. M. Lutterloh; *Treasurer,* Dr. J. T. Altman; *Librarian,* Dr. H. A. Stroud.

The Chicot County (Ark.) Medical Society held its annual meeting at Eudora, April 19, and elected the following officers: *President,* Dr. E. Baker; *Vice-President,* Dr. S. A. Scott; *Secretary and Treasurer,* Dr. Paul E. Johnson.

The McNairy County (Tenn.) Medical Society was organized at a meeting held at Selmer, April 21. The following officers were elected: *President,* Dr. W. H. Hodges of McNairy; *Vice-President,* Dr. J. S. Smith of Selmer; *Secretary,* Dr. W. T. Bell of Selmer; *Treasurer,* Dr. J. R. Smith of Selmer.

The Northampton County (Va.) Medical Society held a meeting in Cape Charles, April 16, and elected the following officers: *President,* Dr. E. W. P. Downing of Franktown; *Vice-President,* Dr. B. H. Gilmer of Townsend; *Secretary,* Dr. Carlisle L. Nottingham of Cape Charles; *Treasurer,* Dr. W. L. Dalby of Bridgetown.

The Plymouth District (Mass.) Medical Society held its annual meeting at Brockton, April 21. The election of officers resulted as follows: *President,* Dr. Wallace C. Keith of Brockton; *Vice-President,* Dr. W. G. Brown of Plymouth; *Secretary and Treasurer,* Dr. Alfred C. Smith of Brockton; *Censors,* Drs. Gilman Osgood of Rockland, Edwin C. Frost, Charles W. Stodder, Arthur L. Beals, and Joseph Frame.

The Windham County (Conn.) Medical Society held its 117th annual meeting at Willimantic, April 21, 1910. The election of officers resulted

as follows: *President,* Dr. G. M. Burroughs of Danielson; *Vice-President,* Dr. J. L. Gardner of Central Village; *Secretary and Treasurer,* Dr. J. H. Egbert of Willimantic; *Councilor,* Dr. J. B. Kent of Putnam; *Censors,* Dr. R. C. Paine of Thompson, Dr. Owen O'Neill of Willimantic, and Dr. C. E. Simonds of Willimantic.

Obituary Notes.—Dr. Herbert Leslie Burrell of Boston, Mass., died at his home April 27, 1910, aged 54 years. He was a graduate of the Harvard Medical School in 1879, and at the time of his death was John Homans Professor of Surgery in Harvard University. During the Spanish-American War Dr. Burrell was chief surgeon of the hospital ship *Bay State,* and he has also been medical director of the First Brigade, M. V. M., and Surgeon General of Massachusetts. In 1907 Dr. Burrell was elected president of the American Medical Association.

Dr. Edson E. Boyd of Ashville, N. Y., died in Erie, Pa., April 19, 1910, aged 78 years. He was a graduate of New York University in 1854 and was a veteran of the Civil War.

Dr. William W. Cole of Allegheny, Pa., died recently at his home, aged 66 years. He was a graduate of the Jefferson Medical College in 1869, and was a member of the Allegheny County Medical Society, and the Medical Society of the State of Pennsylvania. Dr. Cole was a veteran of the Civil War, and at one time physician to the Clifton Springs Sanatorium.

Dr. Calvin M. Fitch of Chicago died April 6 at his country home at Twin Lakes, Wis., aged 81 years. He was a graduate of the New York University Medical College in 1852, and had practised medicine in Chicago since 1856.

Dr. Samuel W. Fletcher of Pepperell, Mass., died at his home on April 12, 1910, aged 77 years. He was a graduate of the Harvard Medical School in 1858. After serving through the Civil War as surgeon in the 32d Massachusetts Regiment Dr. Fletcher settled in Pepperell. He was a member of the Middlesex County Medical Society and the Massachusetts Medical Society.

Dr. John Roberts Haley of Kennebunk, Me., died suddenly at his home, April 21, 1910, aged 53 years. He was a graduate of the Medical School of Maine in 1884.

Dr. Thomas Holmes Kenan of Atlanta, Ga., died on Sunday, April 11, 1910, aged 74 years. He was a graduate of the College of Physicians and Surgeons of Columbia University in 1868, and a surgeon in the Confederate Army. At one time Dr. Kenan was in charge of the State insane asylum at Millidgeville.

Dr. John Nolan of Nichols, Ia., died at his home recently, aged 38 years. He was a graduate of the State University of Iowa and of the St. Louis College of Psysicians and Surgeons in 1895.

Dr. G. C. Purdue of Wichita, Kansas, died April 12, 1910, in New York. He was a graduate of the Northwestern Medical College in 1900, and was a member of the Sedgwick County Medical Society, the Kansas Medical Society, and the American Medical Association.

Dr. Andrew F. Reed of Arlington, Mass., died April 16, aged 61 years. He was a graduate of Dartmouth College in 1871 and of the Harvard Medical School in 1875. He was a member of the Arlington School Board.

Dr. Bigelow T. Sanborn of Augusta, Me., died on April 18, 1910, aged 71 years. He was a graduate of the Medical School of Maine in 1866, since which time he has been connected with the Maine Insane Hospital, of which he has been superintendent since 1883. He was a member of the Kennebec County Medical Society and the Maine Medical Association.

Dr. W. A. Tichenor of Chicago died suddenly in that city April 8, 1910, aged 43 years. He was a graduate of Washington University in St. Louis, and was at one time connected with the State Insane Asylum at Fulton, Mo.

Dr. William M. Miller of McAlevy's Fort, Pa., died on April 22 at the age of 47 years. He was graduated from Jefferson Medical College in the class of 1889. He was a member of the Huntingdon County Medical Society and the Medical Society of the State of Pennsylvania.

Dr. Newton S. Bell of Windsor, Conn., died at his home, April 11, 1910, aged 70 years. He was a graduate of the University of Vermont in 1864 and for over 20 years was health officer of Windsor. Dr. Bell was a member of the Hartford County Medical Society, the Connecticut State Medical Association, and the American Medical Association.

Dr. George F. J. King of Providence, R. I., died April 12, 1910, aged 43 years. He was a graduate of Brown University and of the Medical Department of the University of Pennsylvania in 1898. Dr. King was a member of the Providence District Medical Society, the Rhode Island Medical Society, and the American Medical Association.

Dr. Albert L. Brands of Prairie du Rocher, Ill., died suddenly on April 20, 1910, aged 54 years. He was a graduate of the Missouri Medical College and formerly a State Senator.

Dr. Thomas B. Camden of Parkersburg, W. Va., died at his home April 17, 1910, aged 80 years. Dr. Camden was a graduate of the Jefferson Medical College in 1854. After serving as Superintendent of the Western State Hospital for ten years from 1871, he settled in Wheeling, but soon moved to Parkersburg.

Dr. Havilla C. Hobbs of Salem, Ind., died at his home April 18. He was a graduate of the Eclectic Medical Institute of Cincinnati, and was a member of the Washington County Medical Society, the Indiana State Medical Association, and the American Medical Association.

Dr. Michael H. Lynch of Chicopee, Mass., died at his home, April 16, 1910, aged 52 years. He was a graduate of the University of Vermont in 1882. He was at one time well known as an athlete, having held a championship as a runner.

Dr. Haven Palmer of Plymouth, N. H., died at his home recently, aged 66 years. He was a graduate of the medical department of Bowdoin College in 1871. He was a member of the Grafton County Medical Society, the New Hampshire Medical Society, and the American Medical Association, and at the time of his death was president of the Winnepesaukee Medical Association.

Dr. George T. Twyman of Kansas City, Mo., died April 18, 1910. He was a graduate of the Louisville Medical College in 1879 and was a member of the Jackson County Medical Society, the Missouri State Medical Society, and the American Medical Association.

Dr. James S. O'Brien of Milwaukee, Wis., died April 24, 1910, aged 51 years. He was a graduate of the Rush Medical College in 1885.

Correspondence.

LIVER EXTRACT MEDICATION.

To the Editor of the Medical Record:

Sir:—In an article published in the Medical Record, April 3, 1909, I discussed, upon purely theoretical grounds, the use of liver extract in the treatment of chronic gastro-intestinal autointoxications. Since then I have persuaded the firm of Parke, Davis & Co. to prepare some of this substance and they have placed at my disposal a generous supply. In the cases in which I have used it, the results have been satisfactory, but they are too few in number to warrant definite conclusions. Doses far in excess of the needs of the case were never attended by even the slightest unpleasant symptoms. To any physician desirous of trying the liver extract in a case I will gladly send a share of my supply on the receipt of the history of his case.

O. L. Mulot, M.D.

424 Halsey St., Brooklyn, N. Y.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

R. C. S. PRIZES—REPORT ON ANESTHETICS—LUMLEIAN NOTES CONCLUDED—TREATMENT BY RADIUM—SURGICAL POINTS IN APPENDIX CASES—TUBERCULOSIS EXHIBITIONS—CEREBROSPINAL MENINGITIS—TETANUS SERUM—OBITUARY.

London, April 15, 1910.

You will be interested to hear that at the meeting of the Council of the Royal College of Surgeons yesterday the honorary gold medal of the college was awarded to Dr. Robert Fletcher in recognition of his labors in connection with the *Index Medicus* and the Index Catalogue of the Library of the Surgeon-General's Office, Washington, U. S. A. Dr. Fletcher is a member of the college of the date 1844. He practised here for a time and then left for your side, where he became associated with Dr. Billings, and they projected the Index Catalogue, which the Council pronounce "the most monumental bibliographical work of modern times." Jointly, too, they edited the *Index Medicus*. These facts I would not mention to you only it is in connection with them that the award has been made.

At the same meeting the Jacksonian prize for 1909 was awarded to Mr. William Girling Ball, F.R.C.S., for a dissertation on the treatment of surgical affections by vaccines and antitoxins. The Triennial prize was not awarded. The subject for the next triennial was announced as "The Anatomy and Physiology of the Pituitary Body and the Relationship with Disease of Its Abnormal and Morbid Conditions." The subject of the Jacksonian prize for 1911 will be "Diseases of the Pancreas, with Special Reference to Their Surgical Treatment."

Communications were received from the Privy Council respecting the international conference on cancer research to be held in Paris in October and the International Congress of Medical Electrology and Radiology at Barcelona in September next.

It was determined to publish an illustrated guide to the Hunterian Museum.

The report of the Departmental Committee on the administration of anesthetics was issued on Saturday, and if its recommendations become laws a great reform will be accomplished. At present anyone without any qualification for so serious an action may produce anesthesia by the most potent agents. The committee declare that this state of affairs constitutes a serious menace to the public. They say there is an increasing number of deaths under anesthetics and in the opinion of experts a certain number of them are due to preventable causes. They advise a small standing committee being appointed under the authority of the Home Office. They lay down that no general anesthetic should be administered except by a registered medical or dental practitioner; that dentists should be confined to the use of nitrous oxide and not employ general respirable anesthetics of longer duration; that instruction in the administration of anesthetics should be an essential part of the medical curriculum and such instruction in the use of nitrous oxide an essential part of the dental curriculum. Further, with regard to dentists, it is urged that in no case should the operator administer the gas, but if a medical man be not employed a dental practitioner should be called in for the purpose.

Other recommendations are that every death be reported to the coroner, who should determine whether an inquest should be held. In every case of death under an anesthetic, whether due to it or not, the medical certificate should specify the fact. In the case of death in a hospital or public institution there should be a scientific investigation into the actual cause conducted by the authorities of the institution. Intraspinal anesthesia should be practised only by registered medical practitioners.

"It takes courage to make a diagnosis," said Professor Osler in his Lumleian lectures, and having further remarked that fullness of knowledge and the faculty of looking all round a question may be tempered with doubt, he added another of his characteristic expressions: "A cocksure diagnosis and a positive prognosis may express the assurance of ignorance." In any case of angina pectoris, he said, the first step is to get a clear idea of its nature, and he asked three questions: Is it syphilitic mesoaortitis? Are the arteries involved in a general or local sclerosis? Is it a functional condition without arterial lesion? With regard to the first he showed from his experience the difficulty of deciding and the necessity of never forgetting the possibility of such an explanation. In one case when this condition became recognized after being long unsuspected, the transformation in a month was marvelous. He had not previously thought of a possibility of recovery. As to the real cause of sclerotic cases the lecturer said all agree with Walshe, that the "cardinal fact in the prognosis is uncertainty." The important elements are the individual history, the character of the attacks, and the vascular condition. Much depends on the patient, the life he has led and is willing to lead. He must not burn the candle at both ends. "We doctors are notorious sinners in this respect." It is hard to lessen work when in full swing, harder to give it up entirely. "A severe attack of angina may save a man's life." Long intervals of good health and freedom from attacks may follow the adoption of reasonable habits.

As to functional or faulse angina, Dr. Osler said he had more frequently mistaken the organic form for it than *vice versa*. It is pleasant to hear great authorities describe their errors and the lecturer is always ready to do so in order to extract from them useful lessons. Two of his worst mistakes, he told us, were in cases of medical men, but for their sakes he said he did not regret it, as they both derived great comfort from the opinion that they had not angina. Of another case he read his notes, concluding in favor of a neurotic state, and added: "I was wrong; three years subsequently he died in an attack." Yet another improved so much that he, with the other attendants, congratulated themselves on correct diagnosis and treatment—but the patient "dropped dead at the telephone." The neurotic cases formed two groups, distinguished by the prominence of the vasoconstrictor or vasodilator symptoms. Some cases were toxic (tea, coffee, tobacco), and with the increase of cigarette smoking more may be met with. The lecturer had known three robust men, very heavy smokers, to die as with typical angina. As to treatment, generally he felt some satisfaction for angina: terrible in some aspects, it has circumstances in its favor. It kills late; it kills quickly. We can lessen the sufferings of its victims and cure a certain number. "When a man gets specific aortitis it means he has not had efficient treatment." Mercury and iodide can control the lesion in the arterial wall. The spirochetes are seen in large numbers in the aortic wall, in which they have excited diffuse granulomatous mesoaortitis with destruction of muscle and elastic fibers. The difficulty is its insidiousness, giving no warning. Iodide will clear up the exudate faster than mercury: it will also almost invariably relieve pain. This is its use in aneurysm, too, as good as morphia in the early stage, relieving pain by clearing the exudate in the media and adventitia, and so relieving the pressure on the nerves. In neurotic cases modified Weir-Mitchell cure with hydrotherapy, the wet-pack for vascular ataxia, counterirritation over the heart, etc. In extreme vasomotor ataxia, ergotin. In the severest types of angina all use amyl nitrite to loosen spasm and so relieve pain due to tension. It does not arrest other pain, is not an analgesic, and we often must use morphine to relieve the atrocious pain, or, in despair, chloroform. The first time he gave the last, Dr. Osler said, was with fear and trembling, but he has often used it since without any ill effect. "Theoretically the practise is a bad one," but in his hands and those of the late George Balfour there were no ill effects. For the gen-

eral condition in arterial lesions iodide can be continued for months with intervals. Marchiafava has had great experience and reports well of theobromine, 20 to 30 grains a day. In a middle-aged man who has had an attack it is usually a question of high tension and commencing sclerosis. Drugs have little influence. The habits are the important point. "I usually give two prescriptions—'go slowly' and 'eat less'—on which I find a great many patients put about the same value as did Naaman on the prescription of Elisha."

Some cases treated with radium were shown in the clinical section of the Royal. One was of sarcoma of the ear in a boy of eight. An aural polyp removed last May recurred and was again removed in August. On examination it proved to be sarcoma and Coley's fluid was tried, under which it disappeared but later came back. Radium was then used, with marked improvement, which has continued.

Another case was a growth in the neck in a man of thirty, observed in April last year. It seemed inoperable and grew rapidly. Radium was begun in July, internally and externally, by Drs. Finzi and William Hill. Great local improvement took place, but secondary enlargement in the mediastinal glands occurred. It was described as endothelial. The exhibitors held that it proved the possibility of large and deep malignant growths yielding to radium, but the treatment must be thorough, more so than had been so far the case.

Drs. Finzi and Hill showed also a man of sixty-two with a growth constricting the esophagus in the upper thoracic region. This case they considered an endothelial sarcoma and said that under radium the stricture had become more freely passable.

Mr. Charters Symonds showed again the patient he had shown last December with rodent ulcer and the improvement under radium which had gone on. A bit from the margin showed slight epithelial changes, as in former sections, and considerable small-celled infiltration.

Mr. Lyster said in his trials of radium during eight years he had never seen it influence deep-seated malignant growths. In superficial growths and ulceration it was satisfactory. Rodent ulcer would apparently heal, but it always recurred in his experience. Cancer deeper than about three-fourths of an inch he thought was not affected.

Dr. Lazarus Barlow remarked that all the cases except the rodent ulcer belonged to the indeterminate class, and no one could distinguish those which were malignant from the benign. There was only slight difference between the effects of radium and *x*-rays, and some workers with the latter had developed cancer, a fact suggesting caution to those who thought they were treating cancer.

Mr. Eve recalled a case in which a tumor had entirely disappeared under *x*-ray treatment, and Dr. Herringham referred to one in which a tumor had disappeared and afterward reappeared under the rays.

Dr. Hill, in reply, said he had had seven cases of esophageal growths in which operation had been obviated by radium. He did not say they were cured, but the dysphagia was relieved in them all. The application in the esophagus was practically superficial.

Dr. Finzi also replied, mentioning cases in which definitely malignant growths had disappeared.

Many points in reference to the appendix continue to occupy the surgeons. At the Liverpool Institution on the 31st ult. Mr. R. W. Murray read a paper founded on 151 cases on which he had operated during the last three years, and said he thought the type of the disease differed at present from that met with twenty years ago. Besides the increased frequency of appendicitis, he thought it displayed more virulence. He therefore considered it wise to prepare for operation as soon as diagnosis was certain. The mischief was then confined to the appendix and could be removed with it, the risks being few while the dangers of delay were numerous.

Mr. Rushton Parker said that sometimes the removed appendix had shown no outward change, but on slitting it up there had been found a stricture or other lesion. Early operation had often been justified by finding the appendix in a state of gangrene. Against this was the other fact that patients who had declined operation had recovered and had no second attack. Recovery also in some cases rewarded waiting in apparent recurrency—probably due to adhesions. Again signs of spontaneous recovery have been revealed at operations and account for the disappearance of large, indurated swellings. Such cases were more often seen in preoperation days. In this same way atrophy of the appendix has been observed, amounting almost to its disappearance, and explaining the impossibility of finding it at some recorded operations. Other speakers confirmed the views above stated. Thus Mr. Damer Harrisson agreed that the virulence of appendicitis had greatly increased and Mr. Jeans had been unable to find the appendix in two cases, while Dr. J. C. M. Given mentioned two cases the diagnosis of which seemed clear and operation was advised but refused. Both patients recovered in about thirty-six hours. Such cases suggest greater care in diagnosis.

Yesterday another tuberculosis exhibition was opened in London; this time it is in the St. Pancreas district. The National Association for the Prevention of Consumption intends to carry on this campaign through the country, and the exhibition will be sent to any town desiring to have it. Many applications have already been made. Money is, of course, required and the association has felt straightened for want of it. But yesterday, it was stated at a meeting of the Council, a "well-known philanthropist" had offered to start a special fund to develop the work and a committee was appointed to formulate a scheme. I understand that the sum offered by the generous donor is £500 to begin with, and that he has intimated that in case of need it may be supplemented in the future.

Rumors of cases of cerebrospinal meningitis have prevailed lately and four cases have been reported, three of them this last week. An inquest was held on one in which death had been very sudden, and the friends attributed it to fright, as the man had been a witness in court the day before and there much terrified. The doctor admitted that such mental influence might precipitate an attack if the microbe were already at work. However that might be, the post mortem revealed the cause of death.

In an inquest on a death from tetanus at St. George's Hospital it was said that serum was used, but the supply in England had been exhausted. This is now denied, as the agents of the Lister Institute and other firms had an abundant stock.

Dr. C. E. M. Kelly of Witney, Oxford, died on March 28 from an overdose of morphine which he had taken for the relief of acute pain. He took the diplomas of the conjoint colleges in London in 1891 and at once entered into general practice. Later he determined to graduate at the London University and did so while still in practice. He took the M.B. and B.S. in 1896 and proceeded to M.D. 1897 and M.S. 1898. He also took the Fellowship of the College of Surgeons in 1897. Examinations had no terror for him. He contributed to the Pathological Transactions and to the *Lancet*, chiefly on cancer.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

THE CENTENNIAL OF THE HUFELAND SOCIETY.

BERLIN, March 28, 1910.

IN the early part of February the medical profession of Berlin celebrated the one hundredth anniversary of the founding of the Hufeland Society. Of this society, though the oldest medical association in Berlin, little has been heard during the last few years, as not long ago it was united to the Free Demonstration Society and reorganized. The main purpose of the new revived society is to demonstrate to the practitioners of Berlin rare cases and new methods of treatment. That this foundation has met a long-felt want is shown by the rapid increase in its membership. What Hufeland and his society have meant to Berlin is best shown by the addresses delivered at the celebration. H. Strauss spoke of Hufeland as a physician. Hufeland was the son and the grandson of physicians-in-ordinary to the Court of Weimar, and so from his earliest days he was familiar with questions of medicine and natural philosophy. He took his examinations in Jena in 1783, and was obliged at once to take up the practice of his sick father. He, however, found time for some literary work on the subjects of mesmerism, scrofula, smallpox, and apparent death. His associates included Goethe, Schiller, Herder and Weiland. He was soon made a professor in the University of Jena, where he was a much-sought-after teacher. His lectures were attended by 500 men, his clinical course by 80. In 1796 his best known book, "Die Makrobiotik," made its appearance. The book soon became known in all civilized lands, and was of the greatest influence in improving the standing of the medical profession and spreading the knowledge of hygiene. The author em-

phasized the point especially that the physician is not the master, but the minister of Nature. The physician must seek in every case of disease to make use of the healing power of nature. Dietetics and care of the skin received great stimuli from the works of Hufeland. He was called to Berlin as director of the medical school and as senior physician to the Charity Hospital, where he was a prime mover in the foundation of the university. He was the first dean of the medical faculty, and opened the first polyclinic for poor people. He further took over the leadership of medical affairs in Prussia as privy counsellor and as a member of the state poor directorship. Though he was the physician to the royal household and had an enormous private practice, he lived simply and was ever ready with charity. His college fees he devoted to the sick poor. He refused a patent of nobility, for he held it as a duty that if he was to accept any honors they must be such as the middle classes could enjoy with him.

Von Hansemann spoke upon the subject of Hufeland and the Hufeland Society. On February 1, 1810, Hufeland founded the Medico-Chirurgical Society, which first met at the houses of the officers. The society grew rapidly, and reached the apex of its prosperity in 1833, when Hufeland celebrated the fiftieth anniversary of his doctorate. Since that time the society has borne the name of the Hufeland Society. In 1848 its dissolution was imminent, but Busch succeeded in revivifying it. When, under the influence of Virchow, new societies were formed and increased in importance, the influence of the Hufeland Society decreased. Liebreich, the Berlin pharmacologist, who died not long ago, when president of the Balneological Society, brought about a union with the Hufeland Society and so gave the latter a new lease of life. Finally, the aforementioned amalgamation with the Demonstration Society was accomplished and the permanent success of the society was assured. The speaker told many characteristic tales of Hufeland, the man who was the nucleus around whom the society grew. His noble love of his fellow men and his broad-mindedness showed especially in his work, "Encheiridion," which he wrote for the benefit of the Hufeland Society. The main purpose of his work was to convince his opponents. He had three chief enemies—the English physician, Brown, whose mystic system he fought; Napoleon, who gave so many sad hours to Prussia and to the royal family, to whom he was so frequently called, and ultramontanism, the enemy of many scientific efforts. He sought to decrease his practice in order to be able to devote more time to scientific work. This, however, his patients in most cases refused to allow.

The last address was by L. Brieger. He spoke on Hufeland as a balneologist who visited most of the baths in Germany in order to be able to study each one on the spot. His book, "Praktische Uebersicht über die vorsüglichsten Heilquellen Deutschlands," was of very great value. Even to-day physicians learn much that is useful from these lectures.

At the banquet, which was attended by the greater part of the physicians of Berlin, were distributed some very pretty little souvenirs containing aphorisms and maxims of Hufeland's, collected by Von Riegler and printed by Ambrosius Barth of Leipsic.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

TRANSFORMATION AND DEGENERATION OF PAPILLOMA OF THE BLADDER—SURGICAL GRAFTS ON MAN—RADIOLOGICAL STUDY OF FISTULÆ BY INJECTIONS OF BISMUTH—TRANSVESICAL PROSTATECTOMY—SPOROTRICHOSIS.

PARIS, March 15, 1910.

THE Society of Surgery held, in January, its annual commemorative meeting. The report of the society for the year 1909 was read by Lejars, the annual secretary, and Rochard, secretary-general, read a eulogium of the celebrated surgeon, Professor Berger, who died prematurely during the year. The president for the year 1910 is Dr. Routier.

Tanton, associated professor at Val-de-Grace, presented an interesting observation of a papilloma of the bladder, which, in fifteen years, has recurred four times, and finally developed in the iliac bone an epitheliosarcoma with vesical cells, of which the patient died. Legueu reviewed the interesting points of this observation. Recurrences in papillomatous tumors of the bladder are frequent. In general they do not take place at the point of primary implantation of the first tumor. They occur at other points of the bladder surface. They are generally benign, and we may conclude that papilloma is rather a manifestation of a malady of the vesical epithelium than a tumor, and that that malady has multiple and successive manifestations. The idea of the transformation of benign tumors of the bladder into malignant ones is the belief of the day. They are generally fatal when these tumors are left to themselves. This is the reason why there is a great advantage in operating on these tumors early and not allowing them to go on in their evolution, even when they are not accompanied by alarming symptoms.

Tuffier presented the subject of surgical grafts in the human subject. He has twice transplanted a graft from an animal onto a man, but has obtained two failures. In the first case the graft was of the epidermis of the chicken and frog to cover a large loss of substance by a burn. The epidermis of the animal took perfectly, but after cicatrization was obtained the transplanted portion entirely disappeared in about three weeks. In the second case Tuffier wished to transplant the thyroid body of a dog as a remedy for myxedema. The portion of the thyroid body to be removed, with the usual technique and precautions, were introduced into the atrophied thyroid of the myxedematous subject without any therapeutic success. Tuffier, in a woman who had neither vagina, uterus, nor cervix, did a laparotomy. He found first the tubes with closed orifices, then the fundus uteri, the size and shape of which were normal. Into the incised uterus he introduced a large sound previously covered with a dermoepidermic flap of a sufficient length taken from the thigh. The sound protruded between the labia minora; he closed the uterus and the abdomen and five days later removed the sound. The epidermic fold remained in place and lined the tunnel which had been formed. Curiously enough, from this time onward the patient menstruated regularly and four years later she still had the canal with a lining having the appearance of the epidermic graft; the reflection of the canal of the vagina and cervix uteri had been maintained. Tuffier had also made grafts of osteocartilage to cover articular surfaces after resections. He grafted the articular surface of the head of the humerus onto the extremity of the diaphysis, after resection of the region of the tuberosities. Instead of interposing a fibrous surface to assure movements, he placed an osteocartilaginous surface which, although separated from the body for three-quarters of an hour, took grafting perfectly. The functional result was excellent, and twenty months afterward the mobility of the articulation was still increasing.

Tuffier also has grafted the pieces of a human thyroid body as a remedy for myxedema. He grafted an ovary with its vascular hilum into the broad ligament, then another ovary onto the deep surface of the cellular subcutaneous tissue of the abdomen. These grafts have taken in the majority of cases. The ovary preserves its shape, volume, and special sensibility from three to four years. Finally, Tuffier cited the observation of a venous graft destined to replace a portion of the canal of the urethra. He operated on a man of forty years of age, who presented a perineal fistula, and in whom, after resection of all the fibrous tissue of the perineum, the ends of the urethra were separated by a space of about four centimeters. Some time before Tuffier had resected a large varicose vein in a man of 47. He introduced around a No. 14 sound a segment of the vein; the venous cylinder was exactly applied, so much so that the extremities corresponded to the anterior and posterior portions of the urethra, and filled the loss of substance. All went well until at the end of thirty-six hours the patient, who was very difficult to control, removed the sound. The operation was not a failure, nevertheless, for without having been obliged to pass a sound into the canal the patient urinated through the canal on the twelfth day, 1,200 grams by the meatus, and on the fourteenth day 1,600 grams. Tuffier is so firmly convinced of the possibility of these venous grafts that in a case of ureteral fistula with destruction of about eight centimeters of ureter he proposed to make a ureterovesical autoplasty by the interposition of a venous segment.

Pierre Delbet believes that grafts of the thyroid body cannot be made. They act by their resorption, but do not become grafts; they do not function as organs, but are resorbed, acting as a form of opotherapy during the period of their resorption.

At the Society of Internes, Aubourg showed the use of radiological diagnosis of fistulous tracts by injection of bismuth, and their therapeutic value. By means of the *x*-rays it is impossible to locate exactly a fistulous tract. On the other hand, the injection of bis-

muth for diagnostic purposes has become a method of treatment of fistulæ, the flow from which lessens until cure is complete.

Fourmestraux has obtained excellent results by injections of bismuth and vaseline in tuberculous fistulæ. The results are excellent when the fistulæ are not extensive, but in fistulæ from deep cavities toxic accidents may result from this treatment.

Agasse-Eofont remarked that we must make a distinction between bismuth intoxications according as it is employed internally or externally. Internally the dangerous salt is the subnitrate; externally all the salts of bismuth may become toxic by their transformation into the albuminate of bismuth, in the presence of a wound. This albuminate of bismuth causes subacute accidents essentially characterized by stomatitis, blackened buccal patches, intestinal troubles, and albuminuria. They are serious, frequently fatal.

Dopter read an interesting paper on the serotherapy of cerebrospinal meningitis. The value of this treatment is undoubtedly established by statistics, which show a considerable lessening of mortality, an attenuation of symptoms, and a shortening greater than the total duration of the infection. It is necessary to employ large doses and to repeat them daily up to the disappearance of meningitic symptoms.

Three specimens of transvesical prostatectomy were presented by George Luys, who had operated upon them. These three cases have been followed by three operative and functional successes. The author insisted on the good results from transvesical prostatectomy, which, by preventing the necessity of the sound, have completely rejuvenated the patients, by making them able to become active workers; they empty completely and spontaneously their bladders, the urine is passed by natural and normal micturition, finally the genital functions are not abolished.

A case of sporotrichosis was presented by Paul Salmon. The patient had a large cutaneous gumma, which caused it to be believed that he had tuberculosis or syphilis, but the culture, very easily made, showed the diagnosis to be sporotrichosis, and caused treatment to be instituted with creosote.

Progress of Medical Science.

Boston Medical and Surgical Journal, April 21, 1910.

Treatment of Cervical Rigidity in Obstetrics.—In cases in which great haste is not required, N. R. Mason advises a long hot bath, followed by a copious vaginal injection of hot sterile water. Rupturing the membranes, packing the vagina, introduction of bougies, etc., are all uncertain and objectionable. The packing of the uterine lower segment with sterile gauze is a more reliable method, but the preferable one is to use the elastic dilating bag. The author prefers Voorhes' bag. If the patient is in labor with a rigid cervix we may use obstretric ether, hydrate of chloral, and in primiparæ, the scopolamine-morphine combination. The former drug hastens dilatation and the latter quiets the pain. In regard to the use of ether, it has been pointed out that spasm of the cervical muscle is developed by the pain involved in its dilatation and the early relief of this pain relaxes this spasm and distinctly hastens dilatation. It has also been found that this use of ether does not predispose to post-portem bleeding, prolong the pain or increase the infant mortality. When immediate delivery is called for, we have manual dilatation, the best and safest method, but the hand easily becomes exhausted. In primiparæ the steel instrument must precede the hand. If the cervix can be drawn down into the introitus, we may use the bimanual form of dilatation, then various instruments, the author preferring Newell's, which has four blades manipulated by the hand and not by a screw. The injection into a rigid cervix of one-eighth to one-fourth of a grain of cocaine in 1 per cent. solution may be of assistance. Vaginal cesarean section should be attempted only under ideal surgical conditions. Deep multiple incisions of the cervix are undoubtedly the best method for delivery by the vaginal route. The incisions must be sutured after delivery. Two assistants and a nurse accustomed to "team work" are required, and the operation should be done in a hospital if possible.

Treatment of Acute Dysentery by Intestinal Irrigation with a 5 Per Cent. Solution of Nitrate of Silver.—H. F. Hewes records his experience in a series of ten cases. Each case when first seen was given a dose of sulphate of magnesia. As soon as this drug had acted the irrigation with silver was begun. The rectal tube was inserted from eight to twelve inches and a pint or more, according to the capacity of the patient to hold the solution, was injected. The fluid was retained by the patient as long as possible up to half an hour. Defecation was then allowed. Rectal injections of salt solution were given regularly after each movement during the course of treatment. A second injection of silver nitrate was as a rule given after a period of two days. In some cases only one injection was used. A diet was selected with an idea of reducing the amount of fecal food residue. The daily content of this diet was as follows: Lean meat, 300 grammes; 3 slices of toast with maple syrup; albumin water, consisting of the whites of eight eggs in water. This was continued for five days. The diet was then increased by the addition of more toast, butter, tapioca, potato juice, rice, and macaroni.

New York Medical Journal, April 23, 1910.

The Present Status of Medicine and Its Outlook.—S. F. Butler speaks of present tendencies in the practice of medicine, showing the inclination of many men to run into fads and calling on the laity to support more strongly the present-day practitioner in the crusade for preventive medicine and sanitation. He says that we live in a period of changing order and we must adapt ourselves to the conditions. Reforms in medicine, like political reforms, come largely from outside, originating with the people. Progress in human affairs depends upon the diffusion of intelligence among the people, and progress in medicine offers no exception to the rule. The people must continue to be taught and instructed as to the true relations which should obtain between them and the physician; and this instruction must come from the regular profession. What is needed is more and better knowledge along certain lines. The more general diffusion of knowledge of how to live, which includes an appreciation of the importance of proper hygiene, proper sanitary surroundings, sufficient exercise, a wholesome diet, and so forth; and this would result in the physician being more frequently consulted, but for a different purpose. There would be more frequent detection and suppression of charlatanry and the physician would be consulted in serious cases before it is too late. A more perfect knowledge by the laity of the true relative valuation of regular medicine and the various fads and semi-religious cults, together with a generous appreciation of the limitations of the present state of development of the science, would eliminate most of the false attitudes now held by the public. Then it would be incumbent upon the profession to rid itself of the faults that now are placing it in a position of lessened public favor.

Dreams and Their Relation to the Neuroses,—A. A. Brill presents the following conclusions: (1) As Freud has shown, dreams are perfect psychological mechanisms. They have a definite meaning, and contain a wish fulfilment. (2) Every psychotic symptom is the expression of a former mental occurrence, and symbolically represents a wish fulfilment. (3) The repression of the unconscious is at the basis of both the dream and the psychotic symptom. (4) The dream is the product of the unconscious and hence affords the easiest access to the exploration of the neurosis.

Journal of the American Medical Association, April 23, 1910.

Syphilitic Nervous Diseases.—Joseph Collins holds that the more frequent occurrence of nervous diseases due to syphilis indicates that the present treatment of syphilis is inadequate and the teachings on which it is based harmful and far-reaching in their injuriousness. Iodide of potassium, he thinks, is not strictly antisyphilitic in its action. Its specific action on the spirochete has not been shown. He objects to the idea of parasyphilis and holds that it is universally conceded that tabes, general paresis, a variety of myelitis, meningitis, arteritis, and neuritis are directly due to syphilis. He gives the result of the investigation of a number of cases in which, wherever an intelligent account could be obtained, it was found that iodide of potassium had been given. While Roux and Metchnikoff have proved that mercury destroys the spirochetes there is no such evidence as regards potassium iodide, though this drug removes some of the local manifestations. Furthermore, Collins is of the opinion that the use of the iodide in the early stages of syphilis is not infrequently deleterious by impairing the patient's vitality and interfering with the reaction in the patient's tissues from the effects of mercury. He doesn't favor also the administration of mercury by the mouth and believes that the occurrence of ptyalism is no evidence that it is being taken in sufficient doses to combate the disease. He appreciates the therapeutic possibilities of the iodide but is convinced that it would be better for the thera-

peutics of organic nervous diseases, save in the case of gummatous formations, if the salts of iodine were no longer in use.

Transfusion in Pellagra.—H. P. Cole and G. J. Winthrop reach the following conclusions: 1. Pellagra is an intoxication. 2. The toxin principles of pellagra exist in the blood of pellagrins and will produce pellagrous symptoms when transferred to other animals. 3. Pellagrous serum exhibits definite, precipitative, hemolytic, and antitoxic properties. 4. An artificial immunity can be produced in animals and exists in cured pellagrins. Being interested in the subject of transfusion, they were led to try it in pellagra, not having at the time any knowledge of similar work by others. The difficulty of securing cured patients as donors forced them to employ normal, healthy individuals in a number of their transfusions. These, however, were chosen from among persons living under the same conditions as to infection, as the patients, and might possibly have acquired a certain amount of immunity. They also refer to two cases reported to them by other physicians, as well as to the Italian work in this line. In all the cases there was benefit from transfusion, and except in three fatal cases which were sufficiently accounted for by the advanced stage of the disease or the already hopeless condition, all the other patients, two months after transfusion, are either apparently cured or markedly improved. The authors suggest the following conclusions: 1. Transfusion offers a means of combating the anemia, stimulating the recuperative functions and perhaps of furnishing antitoxic substances to pellagrins. 2. The lessened mortality and marked improvement in transfused pellagrins leads us to anticipate the establishment of a serum therapy in the disease. 3. Transfusion may be offered provisionally as a surgical therapeutic procedure in pellagrous cases pending the perfection of successful serum therapy.

Artificial Vagina.—Referring to a former paper (*Annals of Surgery*, September, 1904) in which he described the operation as performed by him on the cadaver, J. F. Baldwin reports a case of congenital absence of the vagina in a girl of 18, in which he employed his method of restoration of the passage by the transplantation of a portion of the ileum, carefully preserving its mesentery. The recovery from the operation was uneventful and the results very satisfactory. He has operated in four such cases with like results, and similar successful cases have been reported by Mueller and Mori. He prefers using the ileum, though the operation is practicable also with a loop of the sigmoid, as the former is safer.

Torsion of the Omentum.—W. H. Luckett reports a case of torsion of the omentum in which the strangulated portion was found after removal to have twenty-seven complete twists or turns. There was a small adhesion band on the peritoneal side of the hernia cicatrix which probably came off from the lower right-hand corner of the omentum. With a few more twists this probably would have parted and the case have been reported as a pure intraabdominal torsion without adhesion or presence of a hernia. He theorizes over the cause of the torsion and offers the following hypothesis: The structure of the omentum has for its chief framework long thin arteries running downward to its lower border and then upward in the posterior layer to anastomose with the colonic arteries. The veins are about the same and they increase in size and length more rapidly than the arteries during inflammation and have a natural tendency to wrap around the latter and carry the loose mesothelium and, perhaps, may be the chief factor in causing torsion, and he thinks we can add to this the force of the pulsations of the omental arteries. He believes that we must look for a cause within the omentum itself, as where the omentum touches only the smooth wall of the sac, he thinks the possibility of an exterior force is to be excluded in pure hernial torsions.

Filarial Hematochyluria.—C. Wellman and E. von Adelung report a case of filarial hematochyluria treated by thorough cinchonization and subsequent exposure to the *x*-ray, as practised by Wherry and McDill. They reproduce a brief description of the case of those authors and report their own. In conclusion they sum up some of the interesting points noted in the case of their patient as follows: (1) The apparent confirmation of the value of this method of treating filarial hematochyluria; (2) the absence of embryos from the urine even when the case was first seen; (3) the rapid decrease but persistence of a certain number of the microfilariæ in the peripheral night blood during the treatment.

The Lancet, April 16, 1910.

Sterilization of the Skin by the Use of an Alcoholic Solution of Iodine.—H. F. Waterhouse and W. S. Fenwick have abandoned the ordinary scrubbing with soap and water of operative areas. They believe that water thus used causes a swelling of the epithelia and thus prevents an antiseptic from penetrating deeply between the cells and the ducts of the sebaceous and sweat glands. They have tried the iodine painting in 150 cases, all but one being followed by primary union. After various experiments he has settled upon two per cent. of iodine in rectified spirit as the proper solution. Staining of towels is obviated by soaking them in a two and one-half per cent. solution of carbolic acid. The iodine is painted on by an ordinary painter's brush two hours prior to operation, preliminary shaving and any necessary cleansing having been done in time to allow the skin to dry well before applying it. For greater security he paints again in one hour. The last painting is done on the operating table. Superficial hemorrhage is greater than usual as the iodine solution increases the vascularity of the skin. This appears hardened and the knife is dulled more quickly than without the iodine. In certain instances in which it appeared probable that the skin incision might be infected by a discharge from a hollow viscus, it was found advisable to paint the line of incision with the iodine solution each time the wound was dressed. The incision was then covered with dry cyanide gauze. The great advantage in addition to primary union is the time saved in preparation. W. S. Fenwick adds his testimony on the basis of 110 additional cases.

The Occurrence of a Peculiar Protein in the Urine.—The patient of J. Henderson was a miner of forty-seven years, whose principal symptoms were anemia, cachexia, wasting, and the condition of the urine. No malignant disease was discovered and no bone disease. The blood presented all the appearances of a fairly severe secondary anemia. The case was regarded as one of chronic diffuse nephritis. The urine responded to all the usual protein tests, and the protein was precipitated by all the ordinary tests which precipitate protein. It was precipitated with half saturation with ammonium sulphate. After filtration this precipitate was dialyzed against running water and the product left in the sausage paper behaved quite as in the original urine. The ammonium sulphate precipitate was further dialyzed till free from salt and again it showed the same properties. The material obtained from this salt-free product either taken down to dryness in vacuo at a low temperature, or precipitated with alcohol and dried, was found to be a whitish-gray powder, ash-free, and when in solution possessed all the peculiarities of the original body in the urine. The author has at present nothing to add concerning the exact source and nature of this protein.

British Medical Journal, April 16, 1910.

Phlyctenular Affections of the Eye.—S. Stephensen and J. A. Jamieson call attention to the change of view in reference to the relation between phlyctenular affections of the eye and tuberculosis. It was formerly regarded as a strumous affection. Then this idea was given up, but is again to the front. It is now believed that this form of eye affection occurs only in those who are tuberculous. This change of view is based on the following facts: (1) The frequency with which a family history of tubercle can be obtained from these eye cases. (2) The frequent coexistence along with phlyctenular disease of other manifestations of tuberculosis, *e.g.* enlarged glands, otorrhea with or without mastoid disease, pulmonary phthisis, dactylitis, and scrofuloderma. (3) The fact as shown by experimental work that the blood of patients with phlyctenular disease behaves in a manner which is typical of a definite tuberculous infection. (4) The positive result obtained in the phlyctenular cases by employing the usual eye or skin tests for tuberculosis. Out of twenty cases of phlyctenular disease between the fifth and fifteenth year, the von Pirquet case was positive in all. In two cases the inoculation was made more than once before a positive reaction was obtained. Half the cases presented more or less obvious signs of tubercle apart from the inoculations, and fully three-quarters gave a tuberculous family history.

A Series of Cases of Congenital Ophthalmoplegia Externa (Nuclear Paralysis) in the Same Family.—The cases are reported by H. Cooper, whose initial diagnosis was made on a boy of twenty-one years, who came under observation with a small foreign body in the right eye, which was easily removed. There was marked ptosis on both sides, and it was found that all the external eye muscles were paralyzed. The only movement of which

the eyeballs were capable was an almost imperceptible tremor when he made a feeble effort to follow a moving object across the field of vision. Both pupils reacted perfectly to light and accommodation, and sight was normal. The patient stated the condition was congenital. The father had been affected in the same way from birth. Both his father and grandfather had been likewise affected. Of two uncles, one was affected and the other not; of two aunts, neither; of two brothers, one affected and the other not. He had had six children. The first and third died in infancy and were not affected; the second was normal as were also both this man's children; the fourth was the case first mentioned in the paper; the fifth was not affected, and the sixth slightly so. No female member of the family was affected, no case developed after birth, but all were congenital and in all cases but one the child in whom the lesion was but slight have presented almost complete ptosis.

A Case of Poisoning by Camphorated Oil.—F. Barker was called to see a child of sixteen months, who at seven in the evening was discovered drinking camphorated oil from a bottle. She was promptly turned over and then vomited. One hour later she vomited again and in twenty minutes began to have convulsions. The breathing was irregular, face flushed and covered with profuse sweat, pulse was rapid, pupils moderate, equal in size but inactive to light, and there was no conjunctival reflex. The breath did not smell of camphor and the mouth was not sore. The stomach was washed out with warm water until the returned fluid was free from oil and odor. None of the familiar remedies seemed to stop the convulsions except chloroform in small doses. While giving it the fits were preceded by a flickering of the eyelids, the spasms spreading to the abdominal and back muscles, and then to the extremities. There was usually at first conjugate deviation of the eyes and drawing of the mouth to the left followed by turning of both eyes and mouth to the right. On ceasing the chloroform the convulsions became more continuous but less violent, the breathing was decidedly better, and the face of a more natural color. In ten hours after taking the camphor the child went into collapse and died. It was estimated that the amount of solid camphor taken dissolved in the oil was equal to one dram. The author says that apart from the spasmodic action of the respiratory muscles, which joined in the general convulsions, the poison seems to have affected, chiefly, the respiratory center. He utters a warning against the careless handling of what is really a powerful remedy.

The Treatment of Varicose Veins of the Lower Limb by Avulsion.—The method employed by H. D. O'Sullivan will be best understood by his description of a recent case occurring in a man of fifty years. On the evening prior to the operation the limb was shaven and then washed for half an hour with white soap and water. The veins to be removed were then painted with tincture of iodine (*B.P.*), the site of the proposed incisions being marked by broad square patches of iodine. The limb was enveloped for the night in a household towel fresh from the wash. On the morning of the operation, the washing and marking of the limb were exactly repeated. An elastic bandage was applied to the limb, and a tourniquet above the knee. A local anesthetic was employed (cocaine hydrochloride, one gram in one ounce) sterilized by exposure to a temperature of 65° C. for one hour on three successive days. The author thinks, however, that distilled water widely infiltrated is as good as any solution. The longest vein was first dealt with, and the others in exactly similar fashion. It was exposed, immediately below the knee, by a flail-shaped incision, the lesser limb crossing the vein from above downwards. The upper end was tied and allowed to retract after division of the vein. The common origin of the veins at the ankle was next dealt with in similar fashion, the lower end being tied. The longest vein was then exposed and divided by two incisions equidistant from each other and from the ankle and knee, respectively. The cross channels were also exposed at either end and divided. This is essential. A silver probe, with an eye threaded with stout silk, was then passed into the vein from below upwards. The probe was then passed along the lumen of the vein till it emerged at the incision next above. The silk was then firmly tied to the free end of the vein. A firm steady jerk then removed the whole functional vein between the two said incisions. The portions of veins between all the other incisions were then dealt with in similar fashion. The total length of the combined incisions was about seven inches. After suture the incisions were painted with tincture of iodine, and covered with pads of plain boiled lint. On relaxing the tourniquet profuse hemorrhage occurred from each wound, which was easily controlled by the simple pressure of the usual bandage. The blood became diffused throughout the pads and bandage, and the whole quickly set to form a firm and comfortable splint. The bandage and pads were removed on the fourth day. The limb was perfectly free from extravasation and soiling. The wounds were painted with tincture of iodine, and wool and a bandage applied. The sutures were removed on the tenth day. On the fourteenth day the patient got up and walked. The novelty of the operation lies in the complete extirpation of the affected veins through small incisions. In this case some twenty-five inches of vein were removed through incisions of the total length of seven inches.

Miner's Nystagmus.—T. R. Rodger says that nystagmus "against the rule," that is when the eyes are turned downwards instead of upwards, does not seem to have been noticed, but he has now a patient suffering from oscillations and giddiness, and unable to work for two months, but if the patient is made to bend downwards and move his eyes from side to side a very marked oscillation is produced, which persists for a time after the head is raised. There is a history of a similar attack seven years ago following an influenza. The visual acuity is normal no matter in what position the chart is placed relative to the eye level. Both fundi are normal. Hemeralopia is pronounced and giddiness is very troublesome at night. The usual nature of the nystagmus is probably due, according to the author, to the bodily position in which the miners usually work—on their knees instead of on their sides—in the mine in which he has been employed.

Berliner klinische Wochenschrift, April 4, 1910.

Transplantation of a Periosteal-Bone Preparation.—M. Katzenstein reports the case of a boy aged fifteen years who some months previously, following an injury, developed a sarcoma of the lower end of the femur. At operation a section of bone was resected five inches long, extending into the knee joint. Through another incision over the front of the tibia a strip of periosteum five and one-half inches long and four-fifths of an inch broad was incised and a thin lamella of bone, about one-sixteenth of an inch thick attached thereto, was chiseled away. This was so thin that in one place it broke. Under strong traction on the leg this thin strip of periosteum and bone was placed between the two cut ends of the femur; the soft parts were sewed up, and the limb was fixed in plaster of Paris. Three months later on removing the plaster the limb was found to be quite strong, and nine months after the operation an *x*-ray picture of the thigh showed the region of the implanted bone to be nearly as large and as dense as the rest of the bone. There was perfect motility of the knee, and the patient was working regularly on a farm.

Münchener medizinische Wochenschrift, March 29, 1910.

Nonperforated Duodenal Ulcers.—Wilms says that diagnosis of a duodenal ulcer before perforation is a difficult and infrequent procedure. The symptomatology is very indefinite and even on exploratory laparotomy the diagnosis is not easy, duodenal ulcer differing from gastric ulcer in that there is very little thickening around the ulcer, and very often the aid offered by adhesions to surrounding organs is lacking. He, therefore, suggests examining the duodenum from within instead of without. The method of doing this is as follows: Having placed a purse-string suture in the anterior wall of the stomach near the pylorus, an incision is made within the suture. Through this the finger, protected by a rubber finger cot, is passed and the suture is pulled taut. The finger is then passed through the pylorus and the wall of the duodenum is explored. Owing to the extreme shallowness of the ulcers they are not always easy to recognize, and it is often a help to place the gut against the posterior wall of the abdominal cavity or the spinal column. Against these firm backgrounds the thin edges of the ulcers may be more easily felt. When the location and the size of the ulcers have been determined the question arises of treatment. The author considers that a gastroenterostomy in the presence of an intact pylorus is an inadequate procedure, as a certain proportion of the food will go through the pylorus and irritate the ulcers, and, furthermore, with a patent pylorus the gastroenterostomy will close up in a short time. Excision of the ulcer he considers to be unnecessary, and he recommends simply folding the base of

the ulcer in and taking a tuck in the submucosa and serosa. He reports a series of cases so treated.

The Etiology of Hodgkin's Disease and Lymphatic Leukemia.—Fraenkel and Much have studied material from eleven cases of Hodgkin's disease and five of lymphatic leukemia. The glands were stained by the Ziehl and Gram methods, both with and without previous treatment with antiform. From their results they believe that Hodgkin's disease is an infectious disease produced by a Gram positive, antiform-resisting, granular bacillus, which is closely related to the tubercle bacillus. Lymphatic leukemia they also consider to be an infectious disease caused by an acidophilic antiform-resisting bacillus resembling the tubercle bacillus, but several times as large.

Malignant Tumors and Their Development.—Julius Ries offers the hypothesis that malignant tumors grow only from cells in which the nucleus is injured or diseased. Through the disease the nucleus loses the ability to retain the superfluous centrosomes which are present in many cells, and they consequently divide atypically. The author says if one is to make use of this hypothesis for therapeutic purposes one must in the first place, besides removing the malignant cells, make an effort to strengthen the cell nuclei, as, for example, by feeding nuclein-rich food, and finally must seek to paralyze the centrosomes which cause the rapid growth by the same means as are used to stop the activity of the spermatozoa.

Deutsche medizinische Wochenschrift, March 24 and 31, and April 7, 1910.

Etiology of Acute Anterior Poliomyelitis.—H. Bonhoff has studied the central nervous system of two infants which had died from acute anterior poliomyelitis, and in the spinal cord has found certain bodies which he believes to be specific for the disease. The specimens were stained with Mann's stain, having been fixed with sublimate alcohol. The bodies were found within the neuroglia cells of the cord, especially in the regions of the various enlargements, and most particularly of the lumbar enlargement. These cell inclusions lie in the blue stained nucleus and are themselves either a light rose or a darker red color. Their size varies from tiny points to a diameter of 3 to 4 micra. They are sometimes round, sometimes oval, and sometimes one spot is drawn out into a point. The bodies are always surrounded by a light area, well marked off, and in the larger examples they contain one or two tiny bodies in their substance, these latter staining a darker color. The author says that the fact that it has been shown that the virus may be passed through a filter does not disprove the theory that there may also exist larger forms of the infecting organism.

The Production of Chronic Nephritis with Increased Blood Pressure and Arteriosclerosis.—E. Rautenberg has carried on a series of experiments on animals upon the artificial production of nephritis. He summarizes his results as follows: Retention of urine in one kidney of a rabbit for three weeks leads to chronic disease and degeneration of the organ. If the well kidney is then removed the animal may live for several years, exhibiting a chronic nephritis, and finally dying in cachexia. After from one to one and a half years of the disease, autopsy shows regularly a marked sclerosis of the aorta and aneurysm formation. Apparently the increased blood pressure, which is regularly developed, is the primary cause of the arteriosclerosis. Substances with a mydriatic action occur in the blood even earlier than the increased blood pressure appears.

Hemolytic Substances in Gastric Contents.—Erich Fabian has investigated the statement of Grafe and Röhmer that hemolytic substances are demonstrable in the gastric contents of patients suffering from carcinoma of the stomach, while they cannot be found in cases of ulcus ventriculi. In 12 cases of advanced gastric carcinoma the author got positive hemolytic action in seven, and negative in five. In seven cases of ulcer the results were positive in two and negative in five. In one case of gastric lymphosarcoma the reaction was positive. The author gives no explanation of the differences between these results and those obtained by Grafe and Röhmer.

Chvostek's Symptom and Tetany in Older Children.—Oskar Herbst reports the results of a systematic study of a large series of children as to the occurrence of Chvostek's symptom and other signs of spasmophilia or the tetanoid diathesis. He divides his children into two groups for comparison, those between two and six years of age on the one hand, and those from eight to fourteen on the other. Analyzing 300 children, he found that the facial reflex was present in the older ones five times as frequently as in the younger during the last days of October, whereas the following year at midwinter the numbers were nearly equal. This the author believes to be due to the poorer hygienic condition in winter increasing the nutritional and especially the rachitic disturbances in the younger children. He examined 113 pairs of brothers and sisters in school and found that the facial phenomenon was in a considerable majority of the cases more marked in the elder than in the younger. The cases with a marked Chvostek's symptom were given an electrical examination and in practically every case the electrical irritability was found to be increased. The author says that the association between a high-grade Chvostek's symptom and tetany is well proven, but that a further study of the slighter degrees of the facial phenomena is needed. In several cases of outspoken spasmophilia a diet poor in sodium chloride and rich in calcium chloride did not effect the facial phenomenon, but did considerably reduce the electrical excitability.

Suture of the Femoral Artery.—Sonnenburg reports the case of a man in whom the anterior femoral artery was cut almost completely across by a splinter of steel. The diagnosis was difficult, but as the hematoma increased in size an incision was made. The torn ends of the artery were approximated and sutured by the circular method of Carrel. The results were perfect; pulsation returned to the foot; the leg, which was cold, became warm, and the limb was saved.

Drainage of Purulent Arthritis of the Knee by Incision Behind the Condyle.—Riedel says that a suppurating knee joint must be incised before it perforates spontaneously. The typical sites of perforation of the knee joint are the apex of the upper cavity and the popliteal bursa. Incision laterally near the patella, as well as those made posteriorly, avail but little, as the posterior part of the joint remains practically closed, especially in the extended position of the leg. This occurs also when the capsule is split posteriolaterally. If, however, one separates the lateral ligament from the epicondyle, lateral movements of the extended leg are possible, the posterior capsule of the joint falls back, one can hyperextend the crucial ligament, and by placing the leg in a position of slight flexion thorough irrigation of the posterior pockets of the joint is possible. By this method of drainage perforation of pus into the popliteal bursa and into the popliteal fasciæ is best prevented. In the course of time, by scar formation, the lateral ligament again unites with the epicondyle, lateral movements are impossible, and the joint becomes firm. The tibia sinks back slightly, but as it impinges flat upon the femur a useful joint results.

The Action of Mercury and Iodine in Experimental Syphilis.—Tomasczewski has carried out a series of experiments on the action of mercury and iodine in monkeys and rabbits, who have been inoculated with syphilis. He finds that mercury shows a prophylactic action against experimental syphilis in rabbits, but only when used in very large doses. The action of the mercury is in part in increasing the activity of the protective mechanism of the organism, partly in inhibiting development, but mainly in its direct bactericidal action to the specific organism. Iodine shows no protective action; monkeys and rabbits become ill at the regular time, even when they are given a continuous intense treatment from the moment of the injection. The syphilitic lesion of animals, which have been under iodine, heal in a short time under mercurial treatment.

The Diagnosis of the Secretory Function of the Stomach by the X-Ray.—Schlesinger has made use of a procedure for studying the secretion in the stomach quantitatively. He has found that, if a patient who has been fed a bismuth gruel is examined with the *x*-ray at varying intervals after the ingestion of the material, usually three distinct layers may be made out in the shadow picture. The upper layer is clear, due to gas; the lower one is black from the bismuth, and between the two is an intermediate layer giving a faint shadow. This intermediate layer the author believes to be due to the gastric juice, and the width of it to be a quantitative estimate of the secretion of the gastric glands. The method has the advantage that the secretion may be studied during the entire course of digestion.

Book Reviews.

Surgery. Its Principles and Practice. By various authors. Edited by William Williams Keen, M.D., LL.D., Emeritus Professor of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia, and John Chalmers Da Costa, M.D., Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia. Volume V. With 550 illustrations, 45 of them in colors. Philadelphia and London: W. B. Saunders Company, 1909.

The appearance of this, the fifth and last volume of this system of surgery, marks the termination of an enterprise of great magnitude, now brought to a most successful close. What the difficulties are that must be met in collecting and editing the manuscript from so large a number of collaborators (in this case nearly seventy) only those who have engaged in similar work can fully appreciate. As is usual in such cases, the finished work has far exceeded the limits originally planned, but properly few will object to the increase in size of the finished work, which comprises 5500 pages, instead of the 4000 promised. The first 350 pages comprise a monograph of exceptional value by Rudolph Matas, on the surgery of the vascular system, in which he discusses all of the topics to be included under this heading except the ligation of arteries in continuity. As an instance of the progress recent years have seen, it is interesting to note that the surgery of the heart, a topic that perforce has received but scant attention in previous works, now requires 40 pages of text for its presentation. The new technique of arteriorrathy, as developed by the recent work of Carrel, Guthrie, and many others, is also a comparatively new field that is fully described and illustrated. The succeeding 236 pages are devoted to a treatise on operative gynecology by E. E. Montgomery, John M. Fisher, and P. Brooke Bland. The following chapter on surgical technique by John H. Gibbon is thoroughly modern and practical. It includes a description of the various mechanical aids now in use in performing the direct transfusion of blood. W. S. Bickham contributes a chapter on the ligation of arteries, and another on amputations, both of which are beautifully illustrated. Operations on bones and joints are discussed by James P. Warbasse, and plastic surgery by John B. Roberts. In the chapter by William L. Estes on the surgery of accidents, in which the organization of surgical staffs of railroads, and particularly the question of the institution of hospital cars are interestingly discussed. Charles H. Mayo writes on the surgery of the parathyroid glands. The intracranial surgery of the fifth and eighth nerves is discussed by Charles H. Frazier, and Hobart A. Hare contributes a section in general anesthesia. The chapter on local anesthesia was completed by Professor Lennander of Upsala before his untimely death, but the remaining section which had been allotted to him on spinal anesthesia is the work of his assistant, Fredrik Zachrisson. To this the senior editor of the system has added a brief description of Bier's recently published method of venous anesthesia. George E. Armstrong writes on the surgery of the infectious diseases, E. A. Codman on the use of the *x*-ray and radium, and Hampton L. Carson on the legal relations of surgery. The volume closes with a section on laboratory aids in surgical work by William L. Coplin and a discussion of the surgical organization of a hospital by Albert J. Ochsner.

Die Gonorrhoe des Mannes und Ihre Komplikationen. Von San.-Rat Dr. Hans Wossidlo, Spezialartz der Urologie in Berlin. Zweite umgearbeitete Auflage, mit 54 Textabbildungen und 8 teils farbigen Tafeln. Leipzig: Georg Thieme, 1909.

In this second edition, Wossidlo has added new chapters on water-dilating urethroscopy, stricture, and rectal gonorrhea, and revised his treatment of acute gonorrhea. Some sections are rewritten and many paragraphs added, representing the progress of urology since 1903. Under treatment of acute gonorrhea are added the newer santal preparations, silver salts, and accessory instruments for urethral irrigation. The author discusses the points for attainment in the selection of medicaments for irrigation and gives comparisons of the penetrative powers of the different well-known silver salts. He wisely warns against the use of any particular one as routine procedure. The chapters on urethroscopy have been enlarged by the addition of detailed descriptions of the technique of posterior urethroscopy, the appearances of the normal and inflamed mucous membranes, and the changes occurring in the colliculus seminalis caused by gonorrhea as well as by hyperemia due to other factors. The chapter on stricture is a worthy example of condensed writing. The subject receives consideration from all its viewpoints, that of treatment being extremely practical. The recent advances in the pathology and treatment of gonorrheal prostatitis are incorporated, as is also the Bier treatment of gonorrheal arthritis and epididymitis. Five colored and eight uncolored new plates of the urethral picture through the endoscopic tube are added, also three colored plates of stained secretions. The type and workmanship are of superior quality. By extensive literary research enriched with large personal experience, Wossidlo has produced an excellent work, which merits translation into English and a place in the library of every one interested in the subjects of which it treats.

Die topische Diagnose der chronischen Gonorrhoe. Von Dr. Rudolf Picker, emerit. Universitätsassistent, Spezialarzt für Urologie in Budapest. Berlin: Oscar Coblentz, 1909.

This is a small book of 54 pages evolved from previously published articles on the subject in the Hungarian language. The author describes the technique of staining and examining urethral and prostatic secretions, urinary filaments, and flakes. He describes a technique of urethral irrigation with pure cold water in order to obtain filaments from different parts of the urethra for macroscopic and microscopic examination. The technique of urethral and prostatic expression to obtain these secretions is briefly sketched, but detailed description of his method of palpating Cowper's glands is given. Attention is directed to Littrés glands and the Morgagnian crypts and their occasional length. He describes and illustrates by a colored plate a case of intracellular streptococcus infection, which with less microscopic acumen would be readily confounded with gonococci. One-fourth of the book is devoted to case recitals.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles by Leading Members of the Medical Profession Throughout the World. Edited by W. T. Longcope, M.D., Philadelphia, U. S. A. Volume IV. Nineteenth Series. Philadelphia and London: J. B. Lippincott Company, 1909.

The latest volume of this well-known quarterly consists of numerous articles under the headings treatment, medicine, surgery, röntgenology, gynecology, and obstetrics, genitourinary diseases, pediatrics, parasitology, laryngology, and pathology. Among the more notable papers may be mentioned Flexner's Antimeningitis Serum and the Results of its Employment; Bierring's Diagnosis and Treatment of Pernicious Anemia; Longenecker's Color Photographs in Relation to Surgery; Cullen's on the Early Diagnosis of Uterine Cancer; Pisek's on the Diagnosis and Treatment of Congenital Syphilis. Numerous other articles by well-known clinicians and laboratory research workers are to be found in this book, which continues to keep up the high standard of the preceding volumes in this series.

Clinical Studies for Nurses. A Text-Book for Second and Third Year Pupil Nurses and a Hand-Book for All who are Engaged in Caring for the Sick. By Charlotte A. Aikens, Formerly Superintendent of Columbia Hospital, Pittsburg, and of the Iowa Methodist Hospital, Des Moines; Late Director of Sibley Memorial Hospital, Washington, D. C.; Author of "Hospital Housekeeping," "Hospital Training School Methods," and "Primary Studies for Nurses." Illustrated. Philadelphia and London: W. B. Saunders Company, 1909.

The purpose of this work seems to be to collect into one volume the information which nurses are supposed to need on practice, obstetrics, pediatrics, surgery, physical therapeutics, massage, and nervous and mental diseases. In so far as the book confines itself to nursing and the clinical aspect of disease, we can commend it; but it contains matter that cannot possibly concern any nurse in any condition. Sometimes, too, the descriptions are somewhat curious, or are curiously worded. Thus: "The ureter subdivides into several portions, and from these a number of smaller tubes lead into the tissues of the kidney"; "A hernia is an abnormal opening in the walls, etc."; "At birth the uterus when emptied weighs about two pounds"; "Nervous children, as a rule, are not born, but made." The descriptions of methods of diagnosis, with accounts of various kinds of râles and the conditions in which they are found, or Osler's advice to life insurance examiners, or pictures of tuberculous abscess of the humerus or of areas of pericardial effusion and cardiac dulness, do not tend to better nursing ability. The book contains 600 questions for self-examination and review.

Transactions of the American Surgical Association. Volume Twenty-seventh. Edited by Richard H. Harte, M.D., Recorder of the Association. Philadelphia: William J. Dornan, 1909.

This volume contains the papers read before the American Surgical Association at the meetings held June 3, 4, and 5, 1909. The book covers a wide range of surgical activities. Some six-hundred pages are devoted to forty-two papers by such eminent surgeons as Bryant, Ochsner, Halsted, Bloodgood, Finney, Crile, and the Mayo brothers.

Clinical Memoranda for General Practitioners. By Alex. Theodore Brand, M.D., C.M., and John Robert Keith, M.D., C.M. New York: William Wood & Company, 1909.

The authors here voice their experience of many years at the bedside. It is written in the form of paragraphs, most of which are short and to the point. It fairly bristles with helpful advice, including diagnostic, prophylactic, and therapeutic measures, such as the larger books often omit. Part I treats of the medical subjects, Part II of the surgical, Part III of obstetrical and gynecological, and the last part with therapeutics. The book concludes with six pages of aphorisms, little helpful nuggets gleaned from personal experience and much reading.

The points offered to the profession will be particularly helpful to one whose knowledge has been chiefly derived from books. Each one stands out clearly and will make an impression on the reader such as a lengthy description would never do. They are good points, and true. Every practitioner will not agree with everything taught by the authors, but in the main could find but few faults in the ideas expressed.

The Open-Air or Sanatorium Treatment of Pulmonary Tuberculosis. By F. Ruffenacht Walters, M.D., B.S., (London), M.R.C.P., F.R.C.S.; Physician to the Crookesbury Sanatorium; formerly Physician to the Mount Vernon Hospital for Consumptives and Diseases of the Chest; Author of "Sanatoria for Consumptives." New York: William Wood & Company, 1909.

The intention of the author is not only to describe methods applicable to sanatoria, but also to teach the general practitioner how to manage the details of treatment so that he may convert a home into as ideal a place for the patient as is possible. He lays great stress upon detail and the observance of minute points. The use of the vaccine against tuberculosis, and the more indirect method of absorption of toxins, duly regulated by graduated exercise (a process of self-vaccination), are praised by the author. Full descriptions of verandas, tents, and shelters, ventilation methods, heating, and lighting, the avoidance of dust, all serve to make the work of value. The distinctions in the methods employed in the febrile and non-febrile patient, the clothing, baths, and exercise are fully considered. Among many valuable chapters are to be noted special diet lists, useful recipes, and means of disinfection. The second half of the book is more technical and deals with bacteriology, transmission, and predisposing causes of the disease, symptomatology, and treatment. The whole work makes excellent reading for both patient and physician, and the former would not be harmed by its perusal, inasmuch as it deals with easily understood hygiene or with points so technical that he would be unwilling to trust himself with them without advice. The book can be recommended as being the exposition of ideas at present in vogue in the majority of sanatoria in Europe and America.

Diseases of the Heart. By James Mackenzie, M.D., M.R.C.P. Second Edition. New York: Oxford University Press; American Branch, 35 West 32d Street, 1910.

The new knowledge of the heart and the new methods of acquiring it, revealed in Mackenzie's work, have received instant recognition in the speedy exhaustion of the first edition and in the translation of the book into a number of languages. There is little surprising in this, for such a great light as the author has thrown on the subject, and the revolution of the study of cardiac diseases, which the labors of himself and his disciples have brought about could but rivet the attention of the medical world. The old notions of cardiac physiology and pathology have been upset, and the heart has suddenly acquired an importance as an independent organ little inferior to that of the brain itself. The radial pulse and even the ausculatory sounds are no longer the sole or the main criteria of the heart's health, and their diagnostic importance is overshadowed by the signs afforded by the polygraph in the study of the venous pulse, for the latter reveals the condition not only of the left ventricle, but that of the other cavities as well. The interpretation of these signs is not yet established, and herein lies the fascination of their study. In this new edition Mackenzie carries us a little further along, but the changes are not many as yet. There are a number of interesting polygraphic charts at the end of the volume, and there is an appendix by Dr. Lewis on clinical and experimental observations on the electrical changes caused by the contraction of the cardiac chambers, as recorded by the electrocardiograph.

Fundamentals and Requirements of Health and Disease. By Thomas Powell, M.D., Member of the American Public Health Association; the American Health League; and the American Association for the Advancement of Science. Illustrated with many original drawings. Los Angeles and London: The Powell Publishing Company, 1909.

In this volume the author attacks the theory of metabolism and that part of the cell theory which would assume that the white blood corpuscle is the basis of physical life, and substitutes what he calls the vitomotive power. He endeavors to show that foods owe their energy-dispensing attributes to the single element carbon, and that all diseased conditions of the body are primarily due to the action of a single composite substance which he terms "pathogen." The restoration of the afflicted to health depends upon the elimination of this substance. The writer proceeds to show that this may be accomplished by the administration of certain drugs and more particularly by electrodynamic medication, and the use of medicated baths by means of an apparatus invented by him. One cannot escape the impression that the volume is an ingenious plan to make known this apparatus. The claim of having found the origin and the cure of all diseases is such a sweeping assumption that it will need confirmation.

Ophthalmic Surgery. A Treatise on Surgical Operations Pertaining to the Eye and its Appendages, with Chapters on Para-operatic Technic and Management of Instruments. By Charles H. Beard, M.D., Surgeon to the Illinois Charitable Eye and Ear Infirmary; Oculist to the Passavant Memorial Hospital, Chicago; Ex-President of the Chicago Ophthalmological Society; Member of the American Ophthalmological Society. With Nine Plates, Showing 100 Instruments, and 300 Other Illustrations. Philadelphia: P. Blakiston's Sons & Co., 1910.

The author of this work has rendered a signal service to ophthalmology, for he has filled a wide gap in the literature of the subject and has really met a want which has long been felt. All general works on ophthalmology treat more or less fully of the necessary operative procedure, but usually less than more, being concerned chiefly, necessarily and properly, with consideration of pathology, diagnosis, and general treatment. In the present work all the operations which the ophthalmological surgeon may be called upon to perform, on the appendages of the eye, the globe, and the orbit, are minutely described, every step being followed from the preparation of the patient, the selection and care of instruments, and the technique of the operation to the after-treatment. Dr. Beard is gifted with an unusual power of description, and no one with even the most elementary ophthalmological training could fail to understand every detail of the many difficult and delicate operations which he describes. The style is most pleasing, its charm being in its personal character and in the entire absence of didacticism, the reader having the impression of receiving his directions from the lips of the author in an intimate tête-à-tête. To the young oculist the book must prove invaluable and indispensable, and the older and more experienced ophthalmic surgeon will learn something of the history of his specialty, even though he may not need the instruction in operative technique, which the book gives in full measure. There are a number of errors due to hasty proofreading, which will doubtless be corrected in a subsequent edition, which a work of such excellence is bound to have.

A Manual of Normal Histology and Organography. By Charles Hill, Ph.D., M.D., Formerly Assistant Professor of Histology and Embryology, Northwestern University Medical School, Chicago. Second Revised Edition. Philadelphia and London: W. B. Saunders Company, 1909.

This is an elementary manual, in which the fundamental facts of histology are presented in a clear and concise manner, and in which there is as little theory as possible. In this new edition the earlier chapters on the cell and the tissues have been rewritten and enlarged; the rest of the book remaining practically as before. There are ample illustrations, all well selected, and of use.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 7, 1910.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Laryngology and Rhinology, and consisted in a symposium on the recent progress in knowledge and treatment of diseases of the upper respiratory tract.

The Nose and Accessory Nasal Sinuses.—Dr. HENRY L. SWAIN of New Haven, Conn., read this paper. He said that the equilibrium between health and disease was sometimes difficult to analyze, but, expressed in its simplest form, involved, in the case of the nose, first and foremost the complete integrity of the outer layer of the mucous membrane. The whole protective mechanism in the nose was really one of construction and maintenance. If the ciliated epithelium was intact in the nose, germs and deleterious matter were wafted downward and backward into the throat and there disposed of. A free flow of bland serum oozed between the cells of the epithelium and bathed the surfaces, helping to keep the membrane clean. This serum in its healthy state tended to inhibit germ growth; this fluid was also essential to the health and activity of the surface cells and the motility of the ciliæ. Normally there was not much real mucus present on the surface; but when an invader was to be kept away or an irritant kept off, then great activity of the glands afforded an abundant mucus to act as a coating to protect the cells and to enmesh and render innocuous the invaders. Reduced then to its lowest terms, people were all dependent upon the integrity and altertness of the epithelial cells, particularly in the tonsils or lymphoid areas. If the doctors only knew better how to take care of common colds and acute infections, as recently mentioned by Kyle, they would find less opportunity for their surgery; during the last few years, on the whole, they had found it less often necessary to operate, an encouraging sign worth chronicling. Apropos of the perennial question of ozena which often had for its first pathological change the loss of the ciliated epithelium, considerable light had been given to the etiology by properly bringing forward the fact that many so-called ozenic cases were really nothing but obscure cases of sinus disease. Speaking about avenues of research, it had often seemed to Dr. Swain that the conception of the problem of hay fever as it was brought forward by Dunbar was one of the most remarkable and picturesque applications of laboratory research and study to the knowledge and treatment of disease. He regretted that it was not more fruitful in its results. Much progress had been made in obtaining a better knowledge and understanding of the anatomy of the sinuses. Their knowledge of the function of the nose and of the necessity of keeping a healthy mucous membrane made them more careful of turbinate tissues. The use of transillumination and the *x*-ray had been of great service in the diagnosis of sinus disease. In nasal work they had taken advantage of the cutaneous and other reactions such as Wassermann's, the von Pirquet, and the tuberculin. The electric cautery was not used as often nor as freely as it was several years ago. In the last two years more was heard about methods of opening the frontal and other sinuses first thoroughly through the nose before resorting to the external operations which tended to greater or less disfigurement. In this way the nose was kept in better shape to do the work for which it was originally intended. Much had been done during the last two years to make, for instance, an antrum operation intranasally. When certain intracranial complications were present, however, they should open externally in order that they might better see, drain, and care for the collected pus in its dangerous proximity to or in its actual embodiment in the brain substance. From his own experience he said he wished to chronicle that there had been a number of obstinate cases of discharge and scab formation within the nose, as well as some of genuine atrophic rhinitis, in which massolin had been of the utmost help.

The Oropharynx and Nasopharynx.—Dr. W. K. SIMPSON referred to some of the facts and conditions in the naso- and oropharynx, which more or less recently had been the subject of active medical thought. The subject of adenoid vegetations was now recognized as of the most vital importance. Among the most recent advances in the examination of the nasopharynx he mentioned Hay's pharyngoscope; by its use, even in very young patients, a complete picture of the vault of the pharynx might be obtained, thus doing away with the annoyance of digital examination and the difficulty of the ordinary rhinoscopic mirror. Among its benefits might be mentioned the mapping out of various hypertrophies and adhesions about the fossa of Rosenmüller and their removal, under vision, through the anterior nares with the pharyngoscope *in situ*. Through this instrument the Eustachian orifices might be seen, and their catheterization and bougieing accomplished under complete visual control. As in all processes of examination, so in the use of the pharyngoscope, a certain familiarity must be obtained and certain details observed. This instrument could be used almost with equal facility in the examination of the larynx. The recognition of ulceromembranous angina, due to bacillus of Vincent, cleared up many errors and perplexities of previous days, when it was mistaken for syphilis, diphtheria, chronic folliculitis, and other ulcerative conditions. The relation of *Spirochæta pallida* to primary and especially to secondary syphilis of the fauces, played a very important part in recent positiveness of diagnosis of those affections. The present status of serum therapy, exclusive of the diphtheria antitoxin, seemed to have but a limited application to the treatment of inflammatory infections of the pharynx. The use of calcium lactate in immediate and remote operative hemorrhages had received considerable attention and had been followed by beneficial results. The faucial tonsils had also received very much attention, especially as to their anatomy, structure, function, and relation to neighboring healthy and diseased lymphatics, as protective organs, portals of entry to contagious and remote infections, relation to tuberculosis, general and local, rheumatism, scarlet fever, grippe, and other infections, and finally as to the necessity and mode of removal. The profession was becoming convinced that diseased tonsils were a menace to health, and when there was a more widespread understanding of this relation to the health of the individual, the objections to their proper removal would be overcome. It was often a question in Dr. Simpson's mind whether a properly performed tonsillotomy was not as beneficial as an average so-called tonsillectomy. In the performance of the latter operation there was the great lack of unanimity as to the technique by different operators. An attempt should be made toward securing a uniformity of performance.

The Larynx, Trachea, and Bronchi.—Dr. SIDNEY YANKAUER read this paper. After calling attention to the advantages and disadvantages of the various instruments used for examination of the larynx, he said it was his opinion that when the necessary skill in the management of the head lamp had been acquired, the original head illuminating device of Killian was the most satisfactory for bronchoscopic procedures. For direct laryngoscopy, however, where the lumen of the tube was considerably larger, and where the field of observation lay directly at the end of the instrument, the apparatus of Jackson had many desirable conveniences. Three kinds of bacteria

were found in the throats of apparently normal individuals, the staphylococcus, the streptococcus, and the diplococcus. In those severer forms of acute infectious laryngitis, one or more of these germs were found to be the causative agent. These cases were sometimes so rapid in their course that patients succumbed to acute sepsis even before the swelling in the larynx had advanced to a stage in which suffocation threatened; it seemed to him that little could be done in such cases unless an efficient antistreptococcus serum could be found. In tuberculous laryngitis the intralaryngeal operations had been generally abandoned in favor of hygienic, dietetic, and palliative measures. Pregnancy exerted a pernicious influence in such patients; immediate abortion should be considered as urgently indicated as soon as pregnancy supervened. Great advances had been made in the treatment of carcinoma of the larynx by putting into practice the same principles which guided surgeons in the treatment of this disease elsewhere, namely, early operation. When the growth was limited to a small part of the laryngeal interior, laryngotomy might be done and the growth with the surrounding margin of the healthy tissue removed; when the growth extended to the thyroid cartilage, the removal of the entire half of the larynx was indicated; when the growth extended across the median line of the larynx, the entire larynx must be extirpated; if the glands of the neck were enlarged, or if the growth extended beyond the confines of the larynx, and involved portions of the tongue or pharynx, the life of the patient might be prolonged by the very extensive removal of the entire growth *en masse*. The mortality from laryngectomy resulted chiefly from inhalation pneumonia; such an accident could be avoided, according to Gluck, by performing tracheotomy; the trachea was severed completely from the larynx, and its end brought out through the wound and sutured to the skin, thus entirely shutting off the trachea from the wound above. The differential diagnosis of the three chief chronic diseases of the larynx—tuberculosis, carcinoma, and syphilis—had been added by the various blood tests and serum reactions. Radium had been employed in the laryngeal carcinoma and other chronic laryngeal diseases, but the results reported by different observers varied considerably. When applied through the intact larynx, the *x*-ray was entirely without value; when the larynx had been opened, in operable cases, and in recurrences, the use of the *x*-ray limited the growth of the tumor and helped to relieve pain. Since the introduction of the bronchoscope, the diagnosis and treatment of the disease of the trachea and bronchi had been the subject of direct observation and study. Rhinoscleroma occasionally involved the larynx and trachea secondarily; primary scleroma in the larynx and subglottic regions was very rare. He had observed two such cases at Mt. Sinai Hospital; one was cured by applications of the *x*-ray through a tracheotomy wound; in the other the lumen of the trachea had been maintained up to the present time by the repeated passage of a bronchoscopic tube. The most frequent cause of tracheal stenosis was the pressure of the enlarged thyroid gland on that portion of the trachea which passed through this organ. In the milder forms of these stenoses, dilatation by means of Schrötter tubes might cause a sufficient widening of the passage to keep the patient comfortable; in the more pronounced forms, permanent dilatation might be obtained by the introduction of large intubation tubes which must at times be left in place for many weeks. The removal of foreign bodies from the trachea and bronchi had been attended with brilliant results. About five years ago Dr. Yankauer had the privilege of performing the first successful bronchoscopy in this city for the removal of a foreign body. The offending substance was an orange-pit which was inhaled by a child ten months old. It was just large enough to enter the opening of the right bronchus and to project across the bifurcation, so as partly to close the other bronchus. Owing to the small size of the passages, tracheotomy was performed, and the bronchoscope introduced through the tracheotomy wound and the foreign body removed. Recovery was uninterrupted. About one year later he removed a peanut kernel from the right bronchus of a boy of four years, the bronchoscope being introduced through the natural passages. Since that time he had removed two other foreign bodies by the direct method, through the natural passages, and, in association with Dr. Emil Mayer, in a number of other cases both by the direct and indirect methods. The operation for the removal of a foreign body was not a severe one, and, in his own cases, had not lasted more than five minutes. Newer methods of thoracic surgery, by means of which it was now possible to open the chest with impunity, were of interest because of their relation to bronchoscopy; this branch of surgery was as yet in its infancy.

Dr. Harmon Smith opened the discussion on the nose and accessory sinuses, and stated that the protection against the invasion of disease lay not so much in an intact mucosa *per se* as it did in the mucus that was secreted, which performs the mechanical function of constantly washing away any foreign substances. Therefore, anyone advocating the use of salt water, or any of the ordinary antiseptic solutions employed for cleansing purposes, took away from the nasal passages their natural means of protection. Immunity established against infection by such procedures was only temporary, and subsequently rendered the sinuses more susceptible to infection by removing their protection. Dr. Smith had no favorable experience in the use of massolin in purulent conditions. In ozena and atrophic rhinitis it had proven beneficial, in some cases, but it had failed absolutely in others, thus rendering it an uncertain product. Atrophic rhinitis was considered by some authors not a disease of the mucosa primarily, but a disease of the underlying bone, which had extended to the mucosa. One of the great advances in the diagnosis of rhinological subjects had been made in rhinoscleroma, both in isolating the germ causing it and determining its extension to the larynx. The use of the *x*-ray had been very beneficial in the treatment of its external manifestation, and the administration of vaccine had apparently affected it beneficially internally. Dr. Smith said that there were times when the assumption of conservatism relative to any given disease or operation might be construed as progress, and he believed that a conservative consideration of sinusitis was now more advocated than aggressive operative methods. His patients with purulent sinusitis were given every benefit of internal treatment first, and of internal operation second, before proceeding to any external methods. This procedure was adopted in every case except when the ethmoidal or frontal sinus abscess had perforated into the orbit; then immediate operation was performed. The periostitis and general fibrosis following some of the more radical operations were more painful and disagreeable than the previous purulent condition, and, therefore, should lead operators to evacuate the pus with the least possible destruction of tissue. The dangers of neglected sinusitis had been exaggerated, for older observers could recall no instances of death resulting therefrom, and not until the present operative measures were in vogue did they see fatal cases. Of course it had only been recently that post-mortem examinations were directed to the sinuses as a cause of meningitis resulting in death. Abscesses at the base of the brain from sphenoidal or ethmoidal infection had been noted by many, and operations for the same performed. As regards the comfort given the patient, no operation upon the nose exceeded the perfected submucous resection. He believed that it was bad surgery to perform it in chil-

dren under fourteen years of age; in old people its employment depended upon their vitality and the nature of the obstruction. The close relation of the optic nerve to the sphenoidal and ethmoidal sinuses made it easily apparent that infectious or tumorous involvement of either of these localities was reasonably sure to affect the nerve so closely adjacent. Optic neuritis as a complication of empyema of the sphenoidal sinus was of comparatively recent consideration, and operative procedures upon this sinus for the relief of optic neuritis was among their most recent surgical methods. The means of diagnosing sphenoiditis was limited, and no one could say that no periostitis or hyperemic condition existed in the sinus until it was opened. The mere depletion incident to operation on this sinus had been known to affect optic neuritis favorably, so that oculists frequently stated that the last measure for its amelioration be performed, irrespective of the absence of visible sphenoid involvement.

Dr. Lewis A. Coffin reported a case of antrum involvement in which massolin had been used without benefit. A radical operation then was performed, with a resulting cure. With regard to what was said about conservatism in chronic intranasal cases, he did not agree with what had been said; in these cases he believed in a radical operation.

Dr. Lewis A. Frissell continued the discussion, confining his remarks to the consideration of the mouth and pharynx. After briefly reviewing the anatomy of the oropharynx, and the tonsils in particular, he said that the tonsils might act as portals of entry of infection; first, through the blood stream, and, secondly, through the lymph stream, probably the more uncommon method. The diseases that gained access to the body through the oropharynx might be divided into two main types: (1) Those local infections which caused constitutional disturbances by toxic absorption, of which diphtheria was the best example. (2) Those diseases caused by an invasion of the body by bacteria, the most common of which was tuberculosis and the various forms of septic invasion of the body by pyogenic organisms. As would be expected in the cases of organs constantly bathed with tuberculous sputum, a large proportion of the cases show tuberculous tonsils. In children, gland tuberculosis played a very important rôle, and Wohlemuth found that in children under ten years of age 60 per cent. suffered from tuberculous glands. Endocarditis, nephritis, pneumonia, pleurisy, meningitis, phlebitis, skin and eye lesions had all been reported many times as having etiological relationship to tonsillar infections. Rheumatic fever had for a long time been associated with tonsillar invasions. In exanthemata in which throat symptoms formed so important a part it seemed reasonable to postulate a throat infection. Of these scarlet fever and measles stood out prominently.

Dr. Chas. A. Elsberg said that one of the great advances made was in the use of the bronchoscope, and that surgeons must look to the laryngologists for help, for they could teach them a great deal about intrathoracic lesions because of their knowledge of the use of this instrument. Therefore, those working in thoracic surgery must expect aid from the laryngologists. Among the new methods in intrathoracic surgery for overcoming the dangers of pneumothorax he called attention to that of Meltzer and Auer. (See Dr. Elsberg's paper on "The Value of Continuous Intratracheal Insufflation of Air (Meltzer) in Thoracic Surgery," Medical Record, March 19, 1910, page 493.)

Dr. Emil Mayer referred to a case of tracheal scleroma treated by rapid dilatation with the bronchoscopic tube; this was a great advance in the treatment of this condition.

Dr. Walter F. Chappell said he did not believe in radical operations for the acute diseases of the accessory sinuses; in chronic diseases, however, much depended upon intranasal methods when the infection was mild; if the infection was severe and of long standing, then more radical and external measures should be instituted. Rest to the larynx was a very important part of the treatment; he recalled two cases of papillomata of the larynx that he had seen during the past year, in both of which the condition disappeared under complete rest.

Dr. Swain, in closing the discussion, agreed with Dr. Smith that it was not right to wash away the mucus from the nasal passages, and then on a cold winter day to send such a patient out of doors and expect him to improve. That was, in his opinion, about the worst thing that could be done. With regard to tuberculous laryngitis and the use of tuberculin, he said he had cured three cases by giving it in gradually increasing doses. One patient gained seventeen pounds, and, after having been absolutely voiceless and unable to swallow, could now speak and could swallow perfectly.

Stated Meeting Held Thursday, April 21, 1910.

The President, Dr. John A. Wyeth, in the Chair.

A SYMPOSIUM ON FRACTURES AT THE ELBOW.

The Carrying Angle of the Upper Extremity; Its Mechanism and Importance.—Dr. Oscar H. Allis of Philadelphia read this paper. He stated that thirty years ago he had read a paper before the Brooklyn Anatomical and Surgical Society entitled "Deformity from Fractures at the Lower End of the Humerus and How It May Be Avoided." He had also written upon this subject ten years before that time. He had suffered a fracture himself when a child which resulted in "gunstock" deformity and loss of the carrying angle, and his personal experience had early led him to seek the cause and means of prevention of this deformity. Dr. Allis confined his remarks to fractures of the internal condylar region; in his experience these fractures were numerically the most frequent injuries at the elbow joint and occurred oftener in the left than in the right arm. In many of these injuries there was no immediate deformity and hence the fracture might be treated merely as a sprain. The reason for this was in the mechanism of this joint, which gave two distinct borders known as the external and internal supracondylar ridges, each of which was described as having two lips to which were attached important muscles which gave strength to the wrist and hand, and to these ridges were attached the aponeurosis of the muscles on the anterior and posterior aspects of the limb. These attachments, together with those of the deep fascia, gave much strength and support to the lower end of the humerus, and when a fracture took place they gave considerable natural splintage and held the fragments in good position. It was a good rule to give an anesthetic at the first examination, as that examination might reveal any preternatural mobility. In addition the moral effect of the anesthetic was of no trifling value, as it carried with it the presumption of carefulness. In some instances manipulation did not reveal crepitus; this was because the small fragment under discussion had lost connection with the humerus while its ligamentous connection with the ulna had not been disturbed, hence in lateral movements the fragment followed the ulna. In his forty years' experience he had come to regard deformity and impairment of the normal functional activity as of far more importance than the very remote possibility of ankylosis, which was chiefly to be dreaded in injuries of the severest type. In his forty years' experience he had never resorted to an anesthetic to reclaim a joint disabled through bony ankylosis. As to the loss of the carrying angle, he had found that not only did his left arm tire sooner than his right, which was probably due to loss of sup-

port of the elbow upon the pelvic region, but that with the loss of the carrying angle the body leaned toward the deformed arm in order to prevent the object carried from striking against the limbs; this upset the center of gravity and was tiring in the highest degree. Thirty years ago he had attributed the gun-stock deformity to the general practice of using arbitrary manufactured splints, his argument being that the tendency of such a splint was to displace the broken fragment upward because the bandage lifted the ulna, and the ulna, being attached to the broken fragment, displaced it upward. All arbitrary splints were open to the same charge, that of compelling the fragments to approach the splint and thus obliterate the carrying angle. He advocated plastic material that would accommodate itself to the injured part and give support during repair. He preferred the extended position, as he thus had the advantage of a normal limb upon which to mold his dressing. Only in the extended position could he estimate the angle of the normal joint. He applied the plaster bandage so as to include the shoulder of the injured arm, but did not apply the bandage tightly with the purpose of holding the parts in apposition. While the bandage was setting he made a little gentle pressure with a view to flattening it at the elbow. In this position he felt confident of the assistance that the radius could render. He had not been in the practice of removing the splint and resorting to passive motion during repair, but suggested that when passive motion was used the arm be put back into the original splint after very gentle massage and movement. In the dressing of elbow injuries he did not insist upon any arbitrary rule, but held that that position was best which yielded the best results. He had deviated from the extended position in but one case in forty years. Dr. Allis thought that surgeons should not be satisfied with their treatment of these cases so long as the result was lifelong disability and deformity, provided only the patient recovered the single function of motion.

Reconstruction of the Elbow After Fractures of the Lower End of the Humerus.—Dr. John B. Roberts of Philadelphia discussed the varieties of fracture taking place in this region. He held that in the average case the treatment was satisfactory both as to future usefulness of the arm and in regard to its physical contour. The reconstruction, however, depended upon the surgeon having a clear knowledge of the character of the fracture and its method of reduction and upon the selection of dressings which maintained the fragments in the position in which he had replaced them. The possibility of cubitus varus or gun-stock deformity, due to displacement causing adduction of the forearm, had to be remembered. The opposite deformity, cubitus valgus, was said to be far less common than cubitus varus. The use of the *x*-ray might lead to mistaken ideas unless the results obtained by it were subjected to the checks furnished by clinical symptoms and correct understanding of the centers of ossification of the lower end of the humerus. Incision and direct inspection were available means of gaining an accurate knowledge of the line of fracture. This method could only be adopted when the surgeon was familiar with aseptic procedures. The complicated mechanism of the elbow and its association with man's manual dexterity made its reconstruction after osseous lesions an important surgical problem. The deformity called cubitus varus and other deformities might be primary or secondary; hence it was necessary that the reduction of the fragments must be maintained by suitable postures and apparatus. The complicated fractures of the lower end of the humerus, such as occurred from crushing injuries, or gunshot wounds of severity, were liable to give the surgeon trouble. Such fractures were much more apt to be followed by impairment of mobility. Volkmann's contracture of muscles, due to anemia, causing destruction of muscle fibers, probably resulted from tight bandaging or pressure from splints in those cases of fracture in which it occurred as a secondary lesion. It was possible that it might occur from other conditions causing a lack of blood supply to the muscles. The author discussed the extended position of the elbow for the treatment of these fractures and gave it his approval, though he stated that the fully flexed position recommended by Jones, Smith, Scudder, and others was perhaps just as satisfactory. Even the right angle position of the joint might be employed if the surgeon recognized the possibility of cubitus varus and maintained the carrying angle of the arm and forearm during the setting of the splint employed. The correction of deformities or ankylosis by operations such as chiseling, osteotomy, etc., were also discussed. The fixation of the fragments by nails, screws or plugs was referred to and shown to be applicable in some cases. The propriety of using in selected cases a cartilaginous peg taken from the patient's own costal cartilage was also mentioned.

Dr. L. S. Pilcher, in discussing these papers, said that he recollected Dr. Allis' paper read in Brooklyn and had often recalled the views then expressed. The carrying angle was a practical and important entity. After hearing Dr. Allis' paper he had made many measurements upon the arms of children and had found that the angle was really present, and that Dr. Allis had not exaggerated its importance. It was important from a mechanical standpoint and its loss was a real misfortune to those engaged in mechanical arts. While it might not be so important to dwell on one particular method, it was important to keep in mind the relation of these bones and the mechanism of the parts, so that one might be able to appreciate what he had to do; the "how" might be left to the experience of the surgeon, the materials at hand, and the surroundings in the individual case. One experienced with plastic materials would naturally use them, while one accustomed to using other materials might be excused if he followed other methods. He had been impressed with the importance of the aponeuritic structures. The support which they might be made to lend to such an injury was very great. If one used them, outside means might be done away with to a considerable extent. He looked with favor on treatment by such a position as brought into play aponeuritic bands and sheaths and relaxed and lessened the action of those which tended to produce displacement. In his opinion the flexed position relaxed to the greatest degree. From his practical experience he had found that any apparatus which held the part in the flexed position after reposition had been accomplished would do. The flexed position was best both for retention and for comfort, whether by one bandage or another did not make so much difference. Serious loss of function or ankylosis was more frequently due to the presence of exuberant callous. The callous was due to imperfect retention of the parts, constant friction, and increased congestion. It did not become absorbed and remained as a permanent source of interference. In some cases imperfect retention was the result of too frequent attempts to move the joint. After the bones were in position they should be retained there before attempting to subject the arm to function. The natural teaching would be that an injured joint should be kept quiet for at least four weeks. Stiffness quickly disappeared and function was soon restored without interference during this

time. There was too much fear of ankylosis. The care should be to prevent ankylosis by immobility.

Dr. Charles N. Dowd said that the discussion of the advisability of operation and the various methods of retention had led him to wonder whether they were getting better results at present than were obtained some years ago, and consequently he had been looking up old cases. He had seen thirty-four cases treated after Dr. Pilcher's method. The treatment consisted in an examination under ether, putting the fracture up for ten days, then renewing the splint and leaving the arm for three weeks flexed and in as good a position as possible. The results had been scarcely any loss of the carrying angle. There were a few who had lost the carrying angle, but there were no gun-stock deformities. He did not consider the gun-stock deformity a great danger. Perhaps in another series of cases it might occur more frequently. One case of gun-stock deformity was operated upon and then put up in plaster. Three years after the operation the deformity still existed. The dangers of treatment were of two kinds; first, riding back of the lower fragment, limiting flexion. This was one reason why some preferred to put the arm in the flexed position. The second danger was the formation of callous in joints or about fragments. He had had a case some years ago which was up four or five weeks and was very stiff. He wanted to give passive motion under an anesthetic, but Dr. Bull opposed it, as he had seen so many injuries resulting from efforts to force matters. He eventually got good motion in this case, and was grateful to Dr. Bull. Many cases with limited motion would eventually come straight, even though progress was very slow at times.

Dr. Wyeth said that until ten years ago he had treated these fractures in the usual way in the flexed position because he had been so taught, both by books and by surgeons. He had treated many cases and had carried out the rules as intelligently as possible, but his results were unsatisfactory. While investigating the subject he fell upon Dr. Allis' idea and regretted that he had not known of it sooner. He had since used extension. He put the patient under an anesthetic and availed himself of the aid of the fluoroscope when possible. He had also used Dr. Allis' plaster dressing. On the eighth day he removed the dressing as far as the seat of the fracture. He used nitrous oxide gas and flexed the arm to an angle of 45 degrees. Eight days later he repeated the flexion, going as far as 90 degrees. After another eight days he flexed the joint still further, and after this time left no dressing on. He had treated many cases in this way and had had no unsatisfactory results. The majority of cases after long fixation gave limited motion and did not get that degree of extension desirable.

Dr. Reginald R. Sayre said that he had tied the hand as closely to the neck as it was practical to get it. This was a good plan, especially in children. He knotted the bandage closely around the wrist and then around the neck. In a week's time the movements of the neck would draw the hand up considerably. He left the arm in this position until all heat had gone from the elbow. In a few weeks the arm would go back to full extension. He thought that passive motion, especially under an anesthetic, was apt to increase ankylosis. Paralysis might be caused by forced flexion. It was, of course, necessary to preserve the carrying angle, but it should be remembered that many rickety children had knock elbows as well as knock-knees. He agreed with Dr. Allis' statement that the splint should fit the patient, and not the patient the splint.

Dr. Allis, in closing the discussion, thanked the audience for the way in which they had received his paper. The subject was not one that could be minimized. He had just looked over two new books on surgery and found only short paragraphs on this subject, whereas a volume of several hundred pages would be required to do these fractures justice. He regretted that time compelled him to confine his remarks to this one form of fracture, as deformities were apt to occur in all fractures about a joint. Sometimes persons had both arms broken; he had seen two cases in which both arms were in the gun-stock deformity. He wished to emphasize the point that in fractures of the internal condyle nature furnished a good splint, and that anterior posterior pressure should be used in moulding the fragment into position while the plaster was soft. In some severe cases the sharp fragment from above pushed down, injuring the nerve.

Dr. John B. Roberts closed the discussion. He said the carrying angle was greater in some individuals than in others. The way to solve this problem was to look at both arms; the uninjured arm would give the proper carrying angle. He agreed with Dr. Pilcher that partial or full flexion was a very good position to avoid pressure on soft tissues. He also agreed that some cases were more comfortable in this position. It was a bad thing to teach special splints for special fractures. The question was one of mechanism, pathology, and intelligence. Dr. Roberts said that he used to believe that passive motion should be delayed, but he now thought that surgeons sometimes left fractures too long in absolute rest. Most of them did better when properly reduced if looked after daily for a week. They should be manipulated very carefully by someone who understood just what he was doing. He believed in passive motion and in light massage done early and with proper care.

Philadelphia Pediatric Society.

At a stated meeting held April 12 Drs. Z. M. K. Fulton, G. W. Norris, and C. F. Judson demonstrated "Several Cases of Bradycardia Occurring in One Family." The patients consisted of a father and three children presenting varying grades of bradycardia, in some with cyanosis and convulsions, together with graphic evidences of heart-block. The group of cases is unique in showing the possible effect of hereditary influences in the development of disturbances in the structure and function of the connecting bundle of His and the symptoms resulting therefrom. Dr. J. T. Rugh demonstrated a boy on whom he had operated for a large psoas abscess. The condition had manifested itself first by a swelling in the lumbar region and later by a prominence in the groin. Aspiration was practised and bismuth paste injected into the abscess-cavity and, although the affection had been of several years standing, recovery was taking place satisfactorily. Dr. Eleanor C. Jones reported "A Case of General Streptococcic Infection with Symptoms of Empyema." In spite of the fact that elevation of temperature persisted for several months, together with physical signs of a purulent accumulation in the left pleural cavity, multiple puncture failed to effect the evacuation of any fluid, and recovery ensued, with the disappearance of the physical signs. Dr. A. E. Simonis demonstrated a specimen from "A Case of Mitral Disease and Adherent Pericardium." Dr. D. J. Milton presented communication entitled "Personal Observations on the Treatment of Ileocolitis." He employed castor oil as a laxative, and he advised the withdrawal of milk from the dietary, permitting albumin water and beef juice. Dr. E. J. G. Beardsley reported "Two Cases of Nephritis Following Varicella."

Open-Air Schools.—London has three open-air schools for tuberculous children. Similar institutions have been established in the United States in Providence, Boston, New York, Pittsburg, Chicago, Hartford, Conn., Brookline, Mass., and Rochester, N. Y.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NEW HAMPSHIRE STATE BOARD OF MEDICAL EXAMINERS.

January 4 and 5, 1910.

ANATOMY.

1. What are the organs of assimilation, and how does the nourishment get into the circulation?
2. Give a diagram of the eyeball, naming all the parts thereof.
3. What is the relation of the ulna to the elbow and wrist joints?
4. Locate the gall-bladder.
5. Name all the bones that constitute the spinal column.
6. Place and describe the inferior maxillary bone.
7. Enumerate and describe the muscles of the posterior brachial region.
8. What vessels go into and out of the heart?
9. Describe the inferior vena cava.
10. Give the origin, course, and distribution of the facial nerve.

PHYSIOLOGY AND HYGIENE.

1. What is the science of animal physiology?
2. How is the potential energy of food measured, and how expressed?
3. Explain the absorptive process that takes place in the stomach?
4. What is blood pressure, and what are its normal variations?
5. What is the general classification of special reflex movements? Give two examples.
6. What is the physiological process in presbyopia?
7. What comprises the immediate sources of water supply?
8. Give your method of room disinfection after the removal of the patient.
9. What is the best method of garbage disposal in large cities?
10. Discuss quarantine.

CHEMISTRY.

1. What is common table salt? How would you distinguish it from iodode of potassium?
2. Mention some drugs that would be chemically incompatible if combined in a prescription.
3. What are proteids?
4. What is heat?
5. How would you conduct a chemical analysis of urine? Give names and formulæ of all reagents used.
6. Define oxidation and combustion, and give an example of each.
7. Name the chlorine salts of mercury. Give the formulæ, common name, general properties, and toxicity of each.
8. Give in detail a reliable test for the detection of hydrochloric acid in a specimen of gastric contents.
9. What is the difference between an elementary and a compound substance?
10. What is the difference between alcohol and ether?

PATHOLOGY AND DIAGNOSIS.

1. Give symptoms and diagnosis of renal colic.
2. Diagnose between hypertrophy of prostate and tumor of bladder.
3. Give symptoms which would lead you to suspect dilation of heart.
4. Give pathological conditions which produce gangrene.
5. In what pathological condition do you get an excess of earthy phosphates in urine?
6. Give the symptoms and differential diagnosis of pneumothorax.
7. Enumerate the different forms of anemia.
8. Describe a case of rodent ulcer.
9. Give the differential diagnosis between hydatid disease of the liver and other liver diseases.
10. How would you prepare sputum for bacillus examination?

MATERIA MEDICA, THERAPEUTICS, AND THE PRACTICE OF MEDICINE.

1. Give rational treatment for sunstroke.
2. Differentiate laryngeal diphtheria from spasmodic croup and give your treatment for the latter.
3. What cardiac lesions are likely to accompany or to follow acute articular rheumatism and how are they recognized?
4. Give therapeutic indications for the use of chloral hydrate and the appropriate dose in each case.
5. By what rule would you determine the dose of any drug for a child?
6. Without abbreviating, write a prescription containing at least three drugs for acute bronchitis occurring in an adult.

Case: Man, fifty years old, a hard drinker, except during the past year. No family history obtained. For two or three years he has had pain after taking food, occasional vomiting, and progressive loss of flesh and strength. For the past eight or ten weeks he has complained of frequent and severe pain of a "stretching" character in the right hypochondrium, without much tenderness. For the last two weeks he has been deeply jaundiced. For a week he has been confined to bed and is emaciated and prostrated. His nights are disturbed by pain. The liver is greatly enlarged, hard, irregular, and nodulated; the lower edge reaching to the anterior spine of the ilium; it also extends to the left of the median line about two inches. It is slightly tender. There is little or no ascites. Pulse, 92; temperature, 98.5. Urine rather scanty and very dark. No itching of the skin.

7. What diseases can produce emaciation with jaundice?
8. Common cause of hepatic enlargement?
9. What importance would there have been in a good family history?
10. Diagnosis? Prognosis? Treatment?

SURGERY.

1. Enumerate dislocations at shoulder joint and give mode of reduction of each.
2. How would you treat compound fracture of tibia?
3. Enumerate and describe various kinds of aneurysm.
4. Give causes of hematuria and modes of treatment.
5. Describe technique of tracheotomy.
6. Give the etiology, pathology, and symptoms of empyema and describe best operation for its cure.
7. Describe fracture of the patella and describe methods of treatment.
8. Give the symptoms and treatment for fracture at the base of the skull.
9. Describe operation for the radical cure of oblique inguinal hernia.
10. Diagnose fistula in ano and describe operation for its cure.

OBSTETRICS.

1. Under what circumstances would you irrigate after confinement, and with what solutions?
2. Name two of the most frequent non-malignant growths of the uterus.
3. What is the cause of, and how would you treat the frequent inclination to urinate in a pregnant woman?
4. Mention the indications for version.
5. When may an anesthetic be used in a normal labor?
6. What are the causes of sterility in the female, and what is the treatment?
7. What is the treatment for persistent eclampsia a few days previous to labor?
8. Give symptoms and treatment of tubal pregnancy.
9. Give treatment for suppurative mastitis occurring soon after labor for both the mother and the child.
10. Name some of the diseases of pregnancy.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NEW HAMPSHIRE STATE BOARD OF MEDICAL EXAMINERS.

January 4 and 5, 1910.

ANATOMY.

1. The term *assimilation* is "used to cover the subsidiary processes of digestion, respiration, absorption, and excretion, through which food material and oxygen are prepared for the activity of the living molecules, and the waste products of activity are removed from the organism, as well as the actual conversion of dead material into living protoplasm." Hence, *the organs of assimilation* are all the organs of digestion, respiration, absorption, and excretion. The nourishment gets into the circulation by two routes: (1) By the blood-vessels of the gastrointestinal tract, which unite to form the portal vein, and (2) by the lymph vessels of the small intestine, which converge to empty into the thoracic duct. The water, inorganic salts, proteids, and sugar go by way of the portal vein to the ascending vena cava; the fats go by way of the thoracic duct to the junction of the left subclavian and internal jugular vein.

2. See Cunningham's "Anatomy" (1909), page 724; or Gray's "Anatomy" (1908), page 122.

3. The *ulna* is an essential factor of the elbow joint; it does not enter the wrist joint at all, being separated from the first layer of carpal bones by cartilage.

4. The *gall-bladder* is situated in a fossa on the under surface of the right lobe of the liver. It is in relation, in front, with the anterior abdominal wall, immediately below the ninth costal cartilage.

5. Seven cervical vertebræ, twelve dorsal vertebræ, five lumbar vertebræ, sacrum (in youth consisting of five segments), and the coccyx (in youth consisting of four segments).

6. See Cunningham's "Anatomy" (1909), page 142; or Gray's "Anatomy" (9108), page 122.

7. The muscles of the posterior brachial region are the triceps and anconeus. For description see Cunningham's "Anatomy" (1909), page 335; or Gray's "Anatomy" (1908), page 479.

8. *Vessels going into the heart:* Superior vena cava, inferior vena cava, pulmonary veins, cardiac veins, coronary sinus, veins of Thebesius. *Vessels going out of the heart:* Aorta, pulmonary artery.

9. See Cunningham's "Anatomy" (1909), page 892; or Gray's "Anatomy" (1908), page 764.

10. See Cunningham's "Anatomy" (1909), page 686; or Gray's "Anatomy" (1908), page 1059.

PHYSIOLOGY AND HYGIENE.

1. *Animal physiology* is that branch of science which treats of the functions of the organs and tissues of the animal body in a state of health.

2. The potential energy of food is *measured* by the amount of heat or energy that it will produce; it is expressed in *calories.* (A *calorie* is the amount of heat required to raise one gram of water 1° C.)

3. Substances that may be absorbed in the *stomach* are: Water, alcohol, salts, sugars, and dextrins that may have been converted from starch by the ptyalin of the saliva, and proteoses and peptones resulting from peptic digestion of proteids.

4. *Blood pressure* is the force or pressure of the blood exerted against the vessel walls. "In a case of healthy adults, the pressure in the brachial artery ranges between 110 and 130 millimeters of mercury."

5. *Reflexes are classified*: (1) *Superficial reflexes* are such as can be elicited by stimulating the skin. *Example:* The cremasteric reflex. And (2) *deep reflexes* are such as are elicited by stimulating tendons or muscles. *Example:* The patellar reflex.

In the *cremasteric reflex*, irritation of the skin of the upper and inner part of the thigh causes a retraction or drawing up of the testicle. In the *patellar reflex*, if the tendon of the quadriceps extensor is struck with the edge of the hand while the leg hangs loosely over the other leg, there will be a single upward jerk of the leg or foot.

6. *Presbyopia* is due to a gradual failure of the power of accommodation, dependent on the progressive loss of elasticity in the lens and on the loss of its power to increase its refraction. The near point recedes and the range of accommodation is diminished.

7. The sources of water supply are: (1) Rain and snow; (2) surface waters (rivers, lakes, and ponds); (3) subsoil or ground water; (4) deep waters (spring and artesian well).

8. *Method of room disinfection:* All articles that can be disinfected by moist or dry heat or by soaking in some chemical disinfectant should be removed and treated accordingly. All windows, chimneys, and orifices having been closed as tightly as possible, and all cupboards and drawers opened and exposed, the space or chamber should be fumigated in presence of moisture with either formaldehyde, chlorine, or nitrous acid for at least three hours. On re-entering, open all doors and windows, and strip the walls of paper, burn the pieces, have the ceiling well limewashed, and scrub all floors, all woodwork, and furniture with either plain hot water and soft soap, or with bichloride of mercury (1 in 1,000), or with formalin (2 per cent). In many cases adequate disinfection will be secured by free perflation of air, and, in place of fumigation, the free use of a spray of either formalin or mercuric chloride, in the proportions already stated, to the surfaces of walls and furniture. This latter method is probably of greater value than attempts to disinfect by gaseous means, as it is the place itself and not the air of the place we need to disinfect; the air can readily be changed by free ventilation. (From Notter and Firth's *Hygiene*).

9. The best method of garbage disposal in large cities is by cremation.

10. Quarantine has been defined as "the adoption of restrictive measures to prevent the introduction of diseases from one country or locality into another." There are several varieties, such as port quarantine, land, interstate, railroad, municipal, house, and room quarantine. Further, there is quarantine for cattle, also for crops. Most of the leading countries have for a long time been opposed to oppressive, arbitrary, and irrational quarantine measures, and have now adopted rules and regulations, which, while effective as far as can be hoped for or expected, impose the least possible restrictions upon personal liberty and trade. The periods of detention are fixed with reference to the probable incubative period of the disease in question, and questions of the necessity of disinfection and of methods to be followed in carrying out the same are determined by the circumstances of each individual case. Quarantines administered with reason do invaluable work in sifting out infection and protecting the public health from exotic diseases, which, in the absence of precautionary measures, might easily gain access. At the same time they act in restraint of trade to the slightest possible extent, since there is no unnecessary detention. Unfortunately, not all quarantines are administered with reason, and it often happens that great injustice and unnecessary expense are caused by absurdly tenacious adherence to exploded theories and routine practice. (From Harrington's *Hygiene*).

CHEMISTRY.

1. *Common table salt* is sodium chloride. Sodium chloride is insoluble in absolute alcohol, while potassium iodide is soluble in alcohol; further, by the flame test sodium chloride gives a bright yellow color, while potassium iodide gives a violet color.

2. Potassium iodide and mercuric chloride are *chemically incompatible;* so are tincture of cinchona and aromatic spirits of ammonia; also tincture of opium and liquor plumbi subacetatis; likewise glycerin and potassium permanganate.

3. *Proteids* are organic substances of very complex composition and of unknown constitution, which are indispensable to all animal and vegetable life. They are composed of carbon, hydrogen, oxygen, and nitrogen; some also contain sulphur or phosphorus or some other element.

4. *Heat* "is a form of energy into which other forms tend to be converted, which excites peculiar sensations when made to act upon the body; gives rise to luminous phenomena; causes expansion in all bodies and dissociation of their molecules, so as to liquefy solids, evaporate liquids, and rarefy gases, and produces various chemical changes, particularly oxidation and combustion." (Duane's *Medical Dictionary.*)

5. *An analysis of urine* includes: Estimation of total quantity passed in twenty-four hours, color, odor, reaction, specific gravity, total solids (by aid of Haeser's coefficient). Then examine for albumin by Heller's test, or by heat and nitric acid (HNO_3); then for glucose by Moore's test, with potassium hydroxide (KHO), or with Fehling's solution, which contains copper sulphate ($CuSO_4$), sodium hydroxide (NaHO), and Rochelle salt ($C_4O_6H_4NaK$); then for blood with potassium hydroxide solution (KHO); then for bile pigments by Gmelin's test, requiring nitric acid (HNO_3); then for indican, using lead acetate [$Pb(C_2H_3O_2)$], hydrochloric acid (HCl), ferric chloride (Fe_2Cl_6), and chloroform ($CHCl_3$). Then quantitatively for urea, using solution of sodium hypobromite (NaBrO); for chlorides, with silver nitrate solution ($AgNO_3$); for sulphates, with barium chloride solution ($BaCl_2$). Acetic acid ($C_2H_4O_2$) will be necessary to acidify alkaline urines.

6. By *oxidation* we mean the act of union of oxygen with another element or compound. This process is attended by the liberation of heat, and, when it takes place rapidly, of light. The rusting of a given weight of iron is a slow oxidation, while the burning of the same in oxygen is a rapid oxidation. Only the latter produces light, while in both cases the same amount of heat is liberated.

By *combustion*, in a general sense, is meant the rapid union of the oxygen of the air with some other substance, as coal or phosphorus. In a wider sense, however, combustion may be defined as any chemical union of two substances attended by liberation of heat and light.

7. *Mercuric chloride* ($HgCl_2$), corrosive sublimate, is heavy, white, and crystalline; it has a strong, acrid, styptic taste, and is soluble in water, in alcohol, and in ether; it is decomposed by exposure to light. It is very poisonous.

Mercurous chloride (Hg_2Cl_2), calomel, is a heavy, white powder, amorphous, tasteless, and odorless; it is insoluble in cold water and in alcohol, and very slightly soluble in boiling water; when exposed to the light it becomes discolored (first yellow, then gray) and partially decomposed;

it sublimes without fusing; it is incompatible with the mineral acids, with the alkaline chlorides, bromides, and iodides. It is very much less poisonous than mercuric chloride, and is quite frequently administered internally.

8. The Dimethylamido-azobenzol test for free HCl in gastric contents: The reagent is used in 0.5 per cent. alcoholic solution, of which one or two drops are added to a like amount of the filtered gastric juice. If free HCl is present the yellow solution turns red.

9. An *element* is a substance out of which we cannot, by any known means, get any other kind of substance. A *compound* is a substance made up of two or more elements, chemically united, in definite proportions. Thus in an *elementary substance* the atoms are all similar; in a *compound substance* they are not.

10. An *alcohol* is the hydroxide of a hydrocarbon radical. An *ether* is the oxide of a hydrocarbon radical. Thus, ethyl alcohol, C_2H_5OH; ethyl oxide, or ether $(C_2H_5)_2O$.

PATHOLOGY AND DIAGNOSIS.

1. See French's "Practice of Medicine" (1907), page 911; or, Osler's "Practice of Medicine" (1909), page 711.

2. See Rose and Carless' "Surgery" (1908), pages 1226, 1197, and 1200; or, Da Costa's "Surgery" (1908), pages 1187 and 1138.

3. See French's "Practice of Medicine" (1907), page 601; or, Osler's "Practice of Medicine" (1909), pages 821 and 827.

4. *The causes of gangrene* are local or constitutional. Of the former, injuries, mechanical violence, caustics, extremes of heat and cold, as in burns and in frostbites, the application of a ligature, embolic plugging, strangulated hernia, intussusception, ligated hemorrhoids, very tight bandaging, paraphimosis, even extravasation of urine and feces, and continued pressure, as in bedsores, may be given. Of constitutional causes, a deficient blood supply or senile changes may be cited. In certain diseases, as diabetes, typhus, typhoid, measles, and scarlatina, embolism is the usual cause of gangrene. Gangrene from ergotism is due to the effect of this drug on the vessels. Septic gangrene is due to septic infection. (From Gould and Pyle's *Cyclopedia.*)

5. *Excess of phosphates* is found in: Phthisis and other wasting diseases, leukemia, severe anemia, neurasthenia, acute yellow atrophy of the liver, rickets, diabetes, osteomalacia; in some fevers, particularly in the late stages.

6. See French's "Practice of Medicine" (1907), page 703; or, Osler's "Practice of Medicine" (1909), page 658.

7. *Anemias* are: (1) Local; (2) General — Primary — Chlorosis, Pernicious Anemia; Secondary — Pernicious Anemia

8. See Rose and Carless' "Surgery" (1908), page 410; or Da Costa's "Surgery" (1908), page 334.

9. See French's "Practice of Medicine" (1907), page 483; or, Osler's "Practice of Medicine" (1909), page 35.

10. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide, making the smear as thin as possible. Then cover it with some carbolfuchsin and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods, while all other bacteria will appear blue.

MATERIA MEDICA, THERAPEUTICS, AND THE PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1907), page 971; or, Osler's "Practice of Medicine" (1909), page 387.

2. In *laryngeal diphtheria* there is a prior stage of malaise, accompanied by chills, fever, and sore throat. The fever may become very high. A membrane forms, in which are found the Klebs-Loeffler bacillus or streptococci. *Spasmodic croup* generally comes on suddenly, at night. There is no appreciable fever, no previous malaise or sickness, and often the patient is asleep again by the time the physician arrives. There is frequently a thick, tenacious mucus, but neither Klebs-Loeffler bacilli nor streptococci are present. It is entirely a local disturbance. For *treatment of spasmodic croup,* see French's "Practice of Medicine" (1907), page 647; or, Osler's "Practice of Medicine" (1909), page 599.

3. See French's "Practice of Medicine" (1907), pages 226, 559, 570, 577, 581, and 603; or, Osler's "Practice of Medicine" (1909), pages 223, 779, 789, 805, and 809.

4. *Therapeutic indications for use of chloral:* As a hypnotic (in absence of pain), dose gr. xx; as an antiseptic, in a 1 per cent. solution; in cases of acute mania or delirium tremens, dose gr. xx to xxx; in nervous dyspepsia, dose gr. xv; in fevers with high temperature, excitement, restlessness, etc., dose gr. xv; in seasickness, dose gr. v; in tedious labor, to relax a rigid os, and for uterine inertia, dose gr. xx; for nocturnal epilepsy, dose gr. xv; for infantile convulsions, chorea, whooping cough, and laryngysmus stridulus, dose according to age of child, taking adult dose as gr. xv to xx; in tetanus and strychnine poisoning it is said to be antagonistic, dose gr. xx; as an antipruritic, in a solution ten grains of chloral to one ounce of water.

5. *To determine the proper dosage for a child:* Let x = the age of a patient; then $\frac{x}{x+12}$ = the fraction of the adult dose which the patient should receive. Thus, a patient of four years old should receive $\frac{4}{4+12} = \frac{4}{16} = \frac{1}{4}$ of an adult dose.

6. *For acute bronchitis in an adult:*

Recipe:

Ammonii chloridi, grana triginta.
Tincturæ opii camphoratæ.
Syrupi ipecacuanhæ, ana drachmas tres.
Syrupi pruni virginianæ, unciam.
Syrupi Tolutani, quantum sufficiat ad uncias quattuor.

Misce et Signa: Take one teaspoonful every three hours.

The "Case" with questions 7 to 10 is taken from Cabot's *Case-teaching in Medicine;* the answers are taken from the same source.

7. Gallstones and their results, cancer obstructing the biliary passages, syphilis of the liver, cirrhosis, septicemia (toxic jaundice).

8. Passive congestion, biliary obstruction from any cause, fat, cirrhosis, cancer, rickets; rarer causes are abscess, leukemia, pseudo-leukemia, cholangitis, amyloid, and hydatid disease.

9. None in this case.

10. *Diagnosis:* Gastric symptoms, nodular hepatic enlargement with severe pain, with emaciation and jaundice, and without evidence of portal stasis (ascites, etc.), point strongly to *cancer of the liver,* probably secondary to gastric cancer. The history of alcoholism and the hepatic enlargement suggest *cirrhosis,* but there is rarely, if ever, so much pain in cirrhosis (or, indeed, in any liver disease except cancer), and the "hobnails" of cirrhosis are not large enough to make the liver feel "irregular and nodular" through the abdominal wall. The absence of ascites is also against cirrhosis. *Syphilis* of the liver might produce all the signs described, and can only be finally eliminated by the therapeutic test, but the amount of pain here present is almost unknown in syphilis, and the amount of hepatic enlargement is very unusual.

Prognosis: Hepatic cancer usually kills within a year of the discovery of its presence.

Treatment: The relief of symptoms as they arise is all that can be hoped for if the diagnosis is correct, but in all cases of hepatic cancer KI should be given in doses of ten to thirty grains daily until it is proved to be valueless. A patient has been known to die of hepatic syphilis untreated, because her physician was sure it was cancer and had given up hope. The same is true of cirrhosis. All cases should be given KI and the benefit of the doubt whether our diagnosis is correct. The itching which may torture the patient in such cases should be treated by alkaline baths or washes, dilute carbolic washes, or vaseline.

SURGERY.

1. See Rose and Carless' "Surgery" (1908), pages 620 to 623; or, Da Costa's "Surgery" (1908), pages 587 to 592.

2. See Rose and Carless' "Surgery" (1908), page 481; or, Da Costa's "Surgery" (1908), page 464.

3. See Rose and Carless' "Surgery" (1908), page 308; or, Da Costa's "Surgery" (1908), page 356.

4. *Causes of hematuria:* "(1) *Renal hematuria* is due to acute nephritis, calculus, tumors, or injury of the kidneys. Blood casts may be found. (2) *Vesical hematuria* is due to calculus, tumors, injury, cystitis, or the presence of the *Bilharzia hæmatobia.* In the last the ova cause papillomatous tumors in the bladder. (3) *Prostatic hemoturia* is due to congestion, calculus, ulceration, or malignant disease. (4) *Urethral hematuria* is due to catheterism, laceration, or gonorrhea. The blood flows independently of micturition. (5) *Constitutional causes* are purpura, scurvy, hemophilia. Hemoglobin is present, but not

corpuscles, in paroxysmal hemoglobinuria. The spectrum and hemin tests are the most certain, but the guaiacum-ozonic ether test is reliable for urine." (From *Aids to Surgery.*) For *treatment*, see Rose and Carless' "Surgery" (1908); or, Da Costa's "Surgery" (1908), in the Index, under the various conditions mentioned above, under *Causes.*

5. See Rose and Carless' "Surgery" (1908), page 914; or, Da Costa's "Surgery" (1908), page 769.

6. See Rose and Carless' "Surgery" (1908), page 926; or, Da Costa's "Surgery" (1908), page 773.

7. See Rose and Carless' "Surgery" (1908), pages 549 to 553; or, Da Costa's "Surgery" (1908), pages 532 to 538.

8. See Rose and Carless' "Surgery" (1908), page 745; or, Da Costa's "Surgery" (1908), page 709.

9. See Rose and Carless' "Surgery" (1908), page 1081; or, Da Costa's "Surgery" (1908), page 978.

10. See Rose and Carless' "Surgery" (1908), page 1134; or, Da Costa's "Surgery" (1908), page 1009.

OBSTETRICS.

1. *Irrigation after confinement* is done: (1) By some practitioners, as routine treatment after every labor; (2) by others only when there have been repeated vaginal examinations, or (3) in case of foul lochia; (4) or after some operative procedure; (5) in case of sepsis. *Intrauterine douche* is indicated when the hand or instruments have been introduced into the uterus, or when sepsis is suspected. The solutions for *vaginal douche* may be: Hot 1 per cent. creolin mixture in boiled water; or bichloride of mercury, 1:10000 to 1:5000; or decinormal salt solution.

For *intrauterine douche:* Plain sterile water, decinormal salt solution, creolin 1-2 per cent., a bichloride of mercury 1.10000, followed by plain sterile water.

2. Fibroids and polypi.

3. See Hirst's "Obstetrics" (1909), page 251.

4. The *indications for version* are: (1) In transverse presentations; (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed funis; (6) in sudden death of the mother, and (7) in any case where speedy delivery is imperative.

5. See Williams' "Obstetrics" (1909), page 321; or, Hirst's "Obstetrics" (1909), page 329.
